In contrast to the remarkable progress in the chemistry of divalent organic compounds of silicon, germanium and tin, the heaviest congeners of this series, i.e. divalent organolead compounds (plumbylenes), are less investigated. They usually occur as reactive intermediates in the preparation of plumbanes R$_4$Pb and undergo polymerization and/or disproportionation in the absence of suitable stabilizing groups on the lead atom$^{67}$. However, there has been very little information on the dimers of plumbylenes,
i.e. diplumenes. Furthermore, so far no experimental information is available on the chemistry of lead–carbon doubly bonded systems, i.e. plumbenes.

1. Stable plumbylenes

In 1974 the first stable diaminoplumbylene (76) was synthesized by Lappert and coworkers\textsuperscript{68} and since then many other stable plumbylenes with heteroatom substituents have been reported. Recently, the synthesis and characterization of a stable aryl(arylthio)-plumbylene (77), which is one of the rare examples of heteroleptic plumbylenes, have also been reported (Scheme 29)\textsuperscript{69}.

In contrast to the heteroatom-substituted plumbylenes, a few plumbylenes bearing only carbon substituents have been reported. Some of them are stabilized by intramolecular coordination of the lone pair of a donor group in the organic substituent, thus giving the lead a coordination number greater than 2 as can be seen in the diarylplumbylene $R_2^1\text{Pb}$.
(78; $R^f = \text{bis}[2,4,6\text{-tris(trifluoromethyl)phenyl}]$) and the alkylarylplumbylene (79)$^{70}$. On the other hand, kinetically stabilized plumbylenes bearing only organic substituents that do not contain donor groups are scarce, and their structures and reactivities are almost unexplored. The first dialkylplumbylene, $\text{Dis}_2\text{Pb}$ [80; $\text{Dis} = \text{bis}(\text{trimethylsilyl})\text{methyl}]$, was obtained in only 3% yield,$^{57b,c,71}$ and its structure was crystallographically determined recently.$^{72}$ Another dialkylplumbylene 81 with a lead atom in a seven-membered ring system was synthesized and characterized by X-ray diffraction (Scheme 30)$^{73}$. Two stable diarylplumblenes, 82$^{70}$ and 83$^{70}$, were also structurally characterized (Scheme 30). Furthermore, an extremely hindered diarylplumbylene, $\text{Tbt}_2\text{Pb}$: (84), has recently been obtained by the nucleophilic substitution reaction of $[(\text{Me}_3\text{Si})_2\text{N}]_2\text{Pb}$: (76) with two molar amounts of TbtLi as stable blue crystals (Scheme 30)$^{74}$.

SCHEME 30

In all cases mentioned above, the isolated plumbylenes exist as V-shaped monomers, and no evident bonding interaction between the lead centers was observed for the plumbylenes.
either in solution or in the solid state. In other words, until quite recently there has been no experimental information for the existence of a lead–lead double bond (diplumbene), the dimer of plumbylenes.

2. Lead–lead double bonds in the solid state

In 1998, Klinkhammer and coworkers found a quite interesting feature for their new heteroleptic plumbylene Rf[(Me3Si)3Si]Pb: (86)\textsuperscript{75}. Although plumbylene 86 was synthesized by a novel ligand disproportionation between the corresponding stannylene Rf\textsuperscript{2}Sn: (85) and plumbylene [(Me3Si)3Si]\textsubscript{2}Pb:, the crystallographic analysis of the isolated lead product revealed that 86 has a dimeric form 86\textsuperscript{'}, in the solid state with a considerably short Pb···Pb separation [3.537(1) Å] and a trans-bent angle of 40.8° (Scheme 31). Weidenbruch and coworkers also reported the synthesis of another heteroleptic plumbylene (87), the structural analysis of which showed a dimeric structure 87\textsuperscript{'}, in the solid state with a similar short Pb···Pb separation [3.370(1) Å] and a trans-bent angle of 46.5° (Scheme 32)\textsuperscript{70}.

\end{array}
\]

\[Rf = 2,4,6-(CF3)3C6H2\]

\textbf{SCHEME 31}

Although these two plumbylenes 86 and 87 were found to have a close intramolecular contact and exist as a dimer in the solid state, the lead–lead distances in their dimeric form are still much longer than the theoretically predicted values (2.95–3.00 Å) for the parent diplumbene, H\textsubscript{2}Pb=\textsubscript{2}H\textsubscript{2}\textsuperscript{31d,f,76}. In 1999, however, Weidenbruch and coworkers succeeded in the synthesis and isolation of the dimer of less hindered diarylplumbylene Tip\textsubscript{2}Pb: (88), i.e. Tip\textsubscript{2}Pb=\textsubscript{2}Tip\textsubscript{2} (89) (Scheme 33)\textsuperscript{77}. Compound 89 showed a rather shorter Pb–Pb length [3.0515(3) Å] and much larger trans-bent angles (43.9° and 51.2°) than those observed for 86\textsuperscript{'} and 87\textsuperscript{'} strongly indicating that 89 is the first molecule with a lead–lead double bond in the solid state, although 89 was found to dissociate into the monomeric plumbylene 88 in solution. Furthermore, they examined the synthesis of a heteroleptic plumbylene, Tip[(Me3Si)3Si]Pb: (90), by the treatment of diarylplumbylene 88 and disilylplumbylene [(Me3Si)3Si]\textsubscript{2}Pb:. The X-ray structure analysis revealed that the product has the centrosymmetrical diplumbene structure 91 in the solid state (Scheme 33) with a trans-bent angle of 42.7° and a Pb–Pb bond length of 2.9899(5) Å\textsuperscript{78}, which is even shorter than that of 89 and very close to the theoretically predicted value for the parent diplumbene.

In order to elucidate the relationship between the structure of plumbylene dimers and the bulkiness of substituents, Weidenbruch and coworkers synthesized and characterized
much less hindered diarylplumbylene Mes₂Pb: (92), which was isolated as a plumbylene dimer (93) stabilized with coexisting magnesium salt [MgBr₂(THF)₄] (Scheme 34). The large Pb···Pb separation [3.3549(6) Å] and trans-bent angle (71.2°) of 93 suggest that the character of the lead–lead bonding interaction in plumbylene dimers is delicate and changeable.
E. Conjugated Doubly Bonded Systems

In the last few years, further progress has been made in the chemistry of doubly bonded compounds of heavier group 14 elements. The successful isolation and characterization naturally prompted the chemists to examine the synthesis of the more sophisticated systems such as conjugated doubly bonded systems.

Thus, in 1997 Weidenbruch and coworkers have reported the synthesis and isolation of the first stable conjugated Si–Si double-bond compound, i.e. hexatipyltetrasilabuta-1,3-diene \(^{94}\). Tetrasilabutadiene \(^{94}\) was prepared through a rather unique synthetic route starting from the corresponding tetraaryl-substituted disilene \(^{95}\) via the mono-lithiated disilene \(^{96}\) as shown in Scheme 35.

\[
\text{Tip}_2\text{Si} \rightleftharpoons \text{SiTip}_2 \xrightarrow{2\text{Li}} \text{Tip}_2\text{Si} \rightleftharpoons \text{SiTip}(-\text{Li}) \xrightarrow{\text{MesBr}} \text{Tip}_2\text{Si} \rightleftharpoons \text{SiTip}(-\text{Br})
\]

SCHEME 35

In the same year, Tokitoh and coworkers have succeeded in the synthesis and isolation of the first stable 2-silanaphthalene \(^{97}\) by taking advantage of the steric protection afforded by the Tbt group (Scheme 36)\(^{10}\). These two compounds \(^{94}\) and \(^{97}\) should be noted as the first examples which showed that double bonds containing a silicon can make a conjugated system as well as the parent carbon analogues. In 2000, a stable silabenzene \(^{98}\), a much simpler silaaromatic system than \(^{97}\), was also synthesized and isolated using a similar kinetic stabilization method (Scheme 36)\(^9\).

1. Conjugated double-bond compounds containing germanium

Weidenbruch and coworkers have recently succeeded in extending their chemistry of tetrasilabutadiene (\textit{vide supra}) to its heavier congener, i.e. hexaaryltetragermanabuta-1,3-diene \(^{100}\). In this case, tetragermabutadiene \(^{100}\) was prepared from digermene 4 via \(^{99}\) by the synthetic method similar to that of its silicon analogue (Scheme 37)\(^{79}\).

Although the crystallographic analysis of the structure of \(^{100}\) revealed the existence of two Ge–Ge double bonds, no information has been given concerning the possible conjugation between the two digermene units. A more convincing insight was obtained from the electronic spectrum of \(^{100}\). The longest wavelength absorption at 560 nm for
100 in hexane is reasonably interpreted in terms of the bathochromic shifts of those observed for digermenes, which showed yellow or orange color in solution ($\lambda_{\text{max}} = 408–440$ nm)\(^1\text{p},20,23\).

In view of the successful isolation of tetragermabutadiene 100 and its conjugated electronic properties, it may be possible to construct other types of conjugated systems containing germanium atom(s). Actually, Tokitoh and coworkers have recently succeeded in isolating a stable 2-germanaphthalene 101 bearing a Tbt group on the Ge atom\(^81\). The synthesis of germanaphthalene 101 should be noted not only as giving a new example of a cyclic conjugated germene, but also as the first stable example of a neutral germaaromatic compound (Scheme 38).

**Scheme 37**

**Scheme 38**
III. HEAVIER CONGENERS OF KETONES

Carbonyl compounds such as ketones and aldehydes are another important class of doubly bonded systems in organic chemistry. However, their heavier element congeners, "heavy ketones", are much less explored because of the extremely high reactivities.

In the past few decades, almost all of the heavier chalcogen analogues of ketones, i.e. thioketones\textsuperscript{82}, selenoketones\textsuperscript{83}, and telluroketones\textsuperscript{84}, have been synthesized and characterized. Both thermodynamic and kinetic stabilization methods have been applied to stabilize these unstable double-bond species. In contrast to the doubly bonded systems between carbon and heavier chalcogens, heavier group 14 element analogues of ketones are much more reactive and unstable and hence their structures and properties have not been fully disclosed until recently\textsuperscript{85}.

In the series of silicon-containing heavy ketones, however, some suggestive theoretical calculations by Kudo and Nagase\textsuperscript{86} and the first isolation of the thermodynamically stabilized silanethione 102\textsubscript{a,b} by Corriu and coworkers\textsuperscript{87} have strongly stimulated the chemistry of this field (Scheme 39). Then, in 1994 Okazaki, Tokitoh and coworkers reported the synthesis and isolation of the first example of a kinetically stabilized silanethione 103 by taking advantage of steric protection using the extremely bulky aryl group, Tbt (Scheme 39)\textsuperscript{6,88}.

\begin{align*}

(102b) \quad & \text{Ar = } \alpha\text{-Naph}
\end{align*}

SCHEME 39

The detailed background of the chemistry of heavy ketones and the recent progress in the field of silicon-containing heavy ketones has already appeared as a chapter in the previous volume of this series\textsuperscript{85a} and also in other reviews\textsuperscript{88}. Therefore, in the following sections we will discuss the chemistry of the heavier congeners containing germanium, tin and lead. Systematic comparisons for silicon through lead compounds reveal interesting differences in their properties depending on the elements. At first, it may be useful to compile the calculated $\sigma$ and $\pi$ bond energies of all the combinations of doubly bonded systems between group 14 and 16 elements (Table 3)\textsuperscript{6,88}. As can be seen in Table 3 all doubly bonded systems have an energy minimum, suggesting the possibility of their isolation if an appropriate synthetic method is available.

A. Germanium-containing Heavy Ketones

Until recently, there were only two examples of stable Ge–S double-bond compounds and one each for Ge–Se and Ge–Te double-bond compounds, but both of them are stabilized by the intramolecular coordination of a nitrogen ligand to the germanium center.

$^a$ $\sigma$ bond energy.

$^b$ $\pi$ bond energy.

$^c$ Length of the M=X double bond.

$^d$ Value of % reduction in a bond length defined as [(single bond length − double bond length)/single bond length] × 100.

In 1989, Veith and coworkers reported the synthesis of a base-stabilized Ge=S double-bond species 104 (Scheme 40)$^{89}$. The X-ray structural analysis$^{40}$ shows that the sum of the bond angles around Ge atom was 355°, which indicates that the geometry for the Ge atom can be described as distorted tetrahedral, or better still as trigonal planar with an additional bond (N $\rightarrow$ Ge). The Ge=S bond distance of 2.063(3) Å was about 0.2 Å shorter than the value for a Ge=S single bond. The $^1$H NMR spectrum showed three signals assigned to nonequivalent $t$-butyl groups which also indicate this coordination of the nitrogen atom. The synthesis of a germanone bearing the same substituent from the corresponding germylene 105 was also studied (Scheme 40)$^{89a}$, but the trial was unsuccessful, since it resulted in the formation of 106, a dimer of the corresponding germanium–oxygen double-bond species. This is most likely due to the high polarity of the Ge=O bond$^{90}$ in spite of the thermodynamic stabilization.

As another synthetic approach to the doubly bonded systems containing a germanium, Kuchta and Parkin reported the synthesis of a series of terminal chalcogenido complexes of germanium 107, 108 and 109 (Scheme 41)$^{91}$. X-ray structural analyses of 107, 108 and 109 revealed that they have unique germachalcogenourea structures stabilized by the intramolecular coordination of nitrogen atoms but the central Ge−X (X = S, Se, Te) bond of 107, 108 and 109 should be represented by a resonance structure, Ge$^+−X^−$ $\leftrightarrow$ Ge=X.
13. Multiply bonded germanium, tin and lead compounds

Their bond lengths are somewhat longer compared to the sums of theoretically predicted double-bond covalent radii: 2.110(2) Å for Ge=S (107), 2.247(1) Å for Ge=Se (108) and 2.446(1) Å for Ge=Te (109).

1. Synthetic strategies for stable germanium-containing heavy ketones

A variety of preparation methods are known for transient germanium–chalcogen double-bond species; some of them seem to be also useful for the synthesis of kinetically stabilized systems. Indeed, Tokitoh, Okazaki, and coworkers found that the reaction of a germylene with an appropriate chalcogen source is one of the most versatile and general methods for the synthesis of stable germanium-containing heavy ketones (Scheme 42)85b.

SCHEME 42

As in the case of silanethione 103, there has been developed an efficient synthetic method for stable germanethiones and germaneselones, i.e. germanium–sulfur and germanium–selenium double-bond compounds, via dechalcogenation reactions of the corresponding overcrowded germanium-containing cyclic polychalcogenides with a phosphine reagent (Scheme 42)85b. This method is superior to the direct chalcogenation of germylenes in view of the easy separation and isolation of the heavy ketones by simple filtration of the phosphine chalcogenides formed. However, it cannot be applied to the synthesis of germanones and germanetellones due to the lack of stable precursors, i.e. cyclic polyoxides and polytellurides.

\[a. \text{Synthesis of a stable diarylgermanethione.} \]

A series of overcrowded cyclic polysulfides bearing two bulky aryl groups, i.e. 1,2,3,4,5-tetrathiagermolanes 110a–c, have been synthesized as the precursors for kinetically stabilized germanethiones92. The desulfurization of tetrathiolane 110a resulted in the formation of 1,3,2,4-dithiadigermetane 111a, a dimer of germanethione 112a, suggesting that the combination of Tbt and Mes groups is not sufficient to stabilize the reactive Ge=S system (Scheme 43)93.

In contrast, desulfurization of 110b bearing a bulkier Tip group gave germanethione Tbt(Tip)Ge=S 112b without forming any dimer (Scheme 43)94. Although 112b is highly reactive toward water and oxygen, it can be isolated quantitatively under argon atmosphere as orange-yellow crystals. It should be noted that 112b is the first kinetically stabilized isolable germanethione94. It melted at 163–165 °C without decomposition, and no change was observed even after heating its hexane solution at 160 °C for 3 days in a sealed tube. The absorption maximum at 450 nm observed for the orange-yellow hexane solution of 112b was attributable to the n–π* transition of the Ge=S double bond.

Desulfurization of tetrathiagermolane 110c bearing a Dep group, having a bulk between those of Mes and Tip, also gave a dimer of the corresponding germanethione 111c as in the case of 110a (Scheme 43)95. At the beginning of the reaction, however, the electronic spectrum of the hexane solution is reported to show the appearance of a transient absorption at 450 nm attributable to the intermediary germanethione 112e.
These results can be reasonably interpreted in terms of the bulkiness of the protecting groups on the germanium atom, indicating that a combination of Tbt and Tip groups is necessary in order to isolate a germanethione.$^{95}$

**b. Synthesis of a stable diarylgermaneselone.** As in the case of germanethiones, it is known that the treatment of less hindered tetraselenagermolane Tbt(Mes)GeSe$_4$ $^{113a,95,96}$ with triphenylphosphine gives only 1,3,2,4-diselenadigermetane $^{115}$, a dimer of the corresponding germaneselone Tbt(Mes)Ge=Se ($^{114}$), even in the presence of an excess amount of 2,3-dimethyl-1,3-butadiene. This result clearly shows the high reactivity of a germaneselone and the insufficient steric protection by the combination of Tbt and Mes groups (Scheme 44)$^{95}$.

By contrast, Tokitoh, Okazaki and coworkers have reported that deselenation of the bulkier precursor Tbt(Tip)GeSe$_4$ $^{113b}$ with 3 molar equivalents of triphenylphosphine in refluxing hexane under argon resulted in the quantitative isolation of the first stable germaneselone Tbt(Tip)Ge=Se $^{116}$ as red crystals (Scheme 44).$^{95,97}$ Dimerization of $^{116}$ was not observed even in refluxing hexane, in spite of the longer Ge=Se bond distance than that of Ge=S. Germaneselone $^{116}$ was extremely sensitive to moisture but thermally quite stable under inert atmosphere. One can see that the combination of Tbt and Tip groups is sufficiently effective to stabilize the reactive germaselenocarbonyl unit of $^{116}$, as is the case of the germanethione $^{112b}$.

**c. Stable diaryl-substituted germanetellone.** In contrast to the extensive studies on thio-carbonyl and selenocarbonyl compounds,$^{7,8}$ the chemistry of tellurocarbonyl compounds has been much less studied owing to their instabilities.$^{83c,98}$ The chemistry of a germanetellone, the germanium analogue of a tellone, has also been very little explored. Theoretical calculations for H$_2$Ge=Te at B3LYP/TZ(d,p) level have predicted that it has even smaller $\sigma$ (59.1 kcal mol$^{-1}$) and $\pi$ (30.3 kcal mol$^{-1}$) bond energies than those of the
corresponding germanethione and germaneselone, but it still exists at an energy minimum, suggesting the possibility of its isolation. Kuchta and Parkin have already reported the synthesis and crystallographic structure of germatellurourea (Scheme 41), which is stabilized by intramolecular coordination of nitrogen atoms onto the Ge atom, as the only report on the chemistry of germanium−tellurium double-bond species. In view of these facts, the synthesis and isolation of a kinetically stabilized germanetellone are significant not only in order to clarify the character of the Ge−Te double bond by itself, but also to elucidate systematically the properties of germanium-containing heavy ketones.

The successful isolation of stable germanethione and germaneselone suggests that an overcrowded cyclic polytelluride might be a useful precursor for a germanetellone, if it is available. However, no isolable cyclic polytelluride has been obtained, probably owing to the instability of polytellurides. Hence, another synthetic approach was necessary to generate and isolate the germanetellones.

Tokitoh, Okazaki and coworkers have reported that when the stable diarylgermylene, obtained by reduction of the corresponding dibromide with lithium naphthalenide, was allowed to react with an equimolar amount of elemental tellurium in THF, a germanetellone was obtained directly (Scheme 45).

The color change of the solution from blue (λ_max = 581 nm) due to 117 to green (λ_max = 623 nm) was indicative of the generation of a germanetellone. The trapping experiment with mesitonitrile oxide leading to the formation of 37% oxatellurazagermole, the [3+2]cycloadduct of 118, also suggested the generation of 118 as a stable species.
in solution (Scheme 45)\textsuperscript{99,100}. Although this is the first generation and direct observation of a kinetically stabilized germanetellone, an alternative synthetic method for 118 was considered to be necessary for its isolation in view of the low efficiency of its generation and the practical purification procedures.

d. Isolation of a stable germanetellone. Tokitoh, Okazaki and coworkers have reported that when germylene 117, generated from dibromogermane Tbt(Tip)GeBr\textsubscript{2} and lithium naphthalenide, was allowed to react with diphenylacetylene it afforded germirene 120 in good yield as white crystals (Scheme 46)\textsuperscript{101}. This germirene is kinetically stable owing to the bulky groups, in contrast to previously reported germirenes\textsuperscript{102} which are known to be hydrolyzed rapidly in air. They found that germirene 120 was thermally labile and, on heating at 70 °C in the presence of 2,3-dimethyl-1,3-butadiene, it gave germacyclopentene 121 (95%) and diphenylacetylene (100%) with complete consumption of the starting material (Scheme 46). This cheletropic reaction is reversible; in the absence of the trapping reagent, the colorless solution at room temperature turns pale blue at 50 °C showing the regeneration of germylene 117, and becomes colorless again on cooling. These results indicate that germirene 120 is a useful precursor for diarylgermylene 117 under neutral conditions without forming any reactive byproducts (Scheme 46)\textsuperscript{101}.

For the synthesis of germanetellone 118, germirene 120 and an equimolar amount of elemental tellurium were allowed to react in benzene-\textit{d}\textsubscript{6} at 80 °C. On heating the mixture for 9 days and monitoring by \textit{1}H NMR, the appearance of new signals along with those of diphenylacetylene at the expense of those assigned to 120 was observed and the solution turned green. The almost quantitative generation of germanetellone 118 was confirmed by the trapping experiment with mesitonitrile oxide giving the corresponding [3+2]cycloadduct 119 in 94% yield (Scheme 47)\textsuperscript{99,100}. Removal of the solvent from the green solution without the addition of mesitonitrile oxide gave quantitatively germanetellone 118 as green crystals (Scheme 47)\textsuperscript{99,100}. This is the first isolation of a kinetically stabilized germanetellone. Germanetellone 118 was sensitive toward moisture, especially in solution, but thermally quite stable; it melted at 205–210 °C without decomposition.

e. Synthesis of alkyl,aryl-substituted germanium-containing heavy ketones\textsuperscript{85a}. Furthermore, Tokitoh, Okazaki, and coworkers have examined the chalcogenation of an alkyl,aryl-disubstituted germylene, 122\textsuperscript{101}, for a systematic synthesis and isolation of alkyl, aryl-disubstituted germanium-containing heavy ketones (Scheme 48). Germylene 122 was generated by the loss of diphenylacetylene from the corresponding germirene 123 under the conditions similar to those for diarylgermylene 117.
Thermal reaction of germirene 123 was performed in the presence of 1/8 molar amount of S\textsubscript{8} to give germanethione Tbt(Dis)Ge=S (124) quantitatively; it was isolated as yellow crystals in a glove box under pure argon (Scheme 48). Similarly, germaneselone Tbt(Dis)Ge=Se (125) and germanetellone Tbt(Dis)Ge=Te (126) were also synthesized quantitatively and isolated as orange-red and blue-green crystals, respectively (Scheme 48)\textsuperscript{99,103}. In case of germanethione 124, an alternative synthetic route starting from the corresponding tetra(thi)agermolane Tbt(Dis)GeS\textsubscript{4} (127) was examined. The desulfurization of 127 with three molar equivalent amounts of triphenylphosphine in hexane resulted in the formation of the expected germanethione 124 as a major product together with a tetra(thi)adigermacyclohexane derivative 128 as a minor product (Scheme 48).

f. Synthesis of stable dialkyl-substituted germanium-containing heavy ketones. Although there have so far been no reports on the synthesis of kinetically stabilized germanium-containing heavy ketones bearing only alkyl substituents, pentacoordinate germanechalcogenones 130–132 bearing two alkyl ligands were recently synthesized by the chalcogenation of the corresponding base-stabilized germynes 129 (Scheme 49)\textsuperscript{104}. 
Their crystallographic analysis revealed that these pentacoordinate Ge complexes have pseudo-trigonal bipyramidal geometry with a trigonal planar arrangement of the chalcogen and the two carbon atoms around the germanium center. The Ge–chalcogen bond lengths of 130–132 were found to be intermediate between typical single and double bond lengths (vide infra).

### g. Heteroatom-substituted germanium–chalcogen double-bond compounds

In addition to the extensive studies on Ge-containing heavy ketones, there have been recently reported several examples of stable germanium–chalcogen doubly bonded systems having two heteroatom substituents. These include 134\(^{105}\), 136\(^{106}\), 137\(^{106a}\) 139a,b\(^{107}\) and 140a–d (Scheme 50)\(^{107}\) which were mostly prepared by the direct chalcogenation of the corresponding germynes 133, 135 and 138 which are thermodynamically stabilized by the heteroatom substituents.

### B. Tin-containing Heavy Ketones

#### a. Synthesis of stable stannanethiones and stannaneselones

The successful isolation of Si- and Ge-containing heavy ketones naturally provoked the challenge for the synthesis and isolation of the much heavier congeners, i.e. tin–chalcogen doubly bonded systems. However, the combination of Tbt and Tip groups is not bulky enough to stabilize the stannanethione Tbt(Tip)Sn=S 141\(^{108}\), in contrast to the lighter analogues such as silanethione 103 and germanethione 112b.

Although the stability of stannanethione 141, which was generated in the sulfurization of the corresponding stannylene Tbt(Tip)Sn: (142) with elemental sulfur, was evidenced by the characteristic absorption maxima (\(\lambda_{\text{max}} = 465\) nm) in its electronic spectra, concentration of the reaction mixture resulted in the dimerization of 141 giving 1,3,2,4-dithiadistannetane derivative 143 (Scheme 51)\(^{108a,c}\). Stannanethione 141 can also be formed in the desulfurization of the corresponding tetraethylstannolane 144 with triphenylphosphine, but the formation of 141 has been confirmed only by trapping experiments (vide infra)\(^{108b}\) and the \(^{119}\)Sn NMR chemical shift for the central tin atom of 141.

SCHEME 51

The high reactivity of tin–chalcogen double bonds was somewhat suppressed by the modification of the steric protection group combined with the Tbt group from the Tip group to more hindered ones such as 2,4,6-tricyclohexylphenyl (Tcp), 2,4,6-tris(1-ethylpropyl)-phenyl (Tpp) and 2,2''-dimethyl-m-terphenyl (Dmtp) groups110,111. Thus, in these bulkier systems, the corresponding stannanethiones (148, 151 and 154) and stannaneselones (157, 160 and 163), formed respectively from 147, 150 and 153 and from 156, 159 and 162, showed characteristic orange and red colors, respectively, and all of them showed considerably deshielded $^{119}$Sn NMR chemical shifts ($\delta_{\text{Sn}} = 467$ to 643 ppm) at ambient temperature, suggesting the $sp^2$ character of their tin centers and also their stability in solution (Scheme 52). On concentration of the samples used for the NMR measurements, however, these tin-containing heavy ketones underwent dimerization to give the corresponding dimers (149, 152, 155, 158, 161 and 164) although it was unsuccessful in isolating them as a stable solid or crystallines.

As the final goal of the synthesis and isolation of tin–chalcogen double-bond species, further modification of Dmtp group was examined111. Thus, the fine tuning of the side chains of the terphenyl unit of Dmtp, i.e. the use of 2,2''-diisopropyl-m-terphenyl (Ditp) group which bears two isopropyl groups instead of methyl groups in 2 and 2'' positions, allowed isolation of the corresponding stannanethione 166 and stannaneselone 168 as stable orange and red crystals, respectively. Both 166 and 168 were synthesized by the dechalcogenation of the corresponding Tbt- and Ditp-substituted tetrachalcogenastannolanes 165 and 167 with three equivalents of phosphine reagents (Scheme 53)111. No dimerization of 166 and 168 was observed even after concentration to the solid state, and the molecular geometry of stannaneselone 169 was definitively determined by X-ray crystallographic analysis.

In addition to the successful isolation of the stable stannaneselone 168, it should be noted that deselenation of 167 with two molar equivalents of triphenylphosphine resulted in the isolation of a novel tin-containing cyclic diselenide, i.e. diselenastannirane 169, as a stable crystalline compound111.

SCHEME 53
C. Lead-containing Heavy Ketones\textsuperscript{74b}

a. Synthesis of plumbanethiones by desulfurization of tetrathiaplumbolanes. In anticipation of kinetic stabilization of a plumbanethione, the heaviest congener of metallanethiones of group 14 elements, a series of hindered tetrathiaplumbolanes 170–172, were desulfurized with 3 equivalents of hexamethylphosphorous triamide at low temperature (−78 °C) in THF. The color of the reaction solution turned red for 170 and 171 or orange for 172, indicating the generation of plumbanethiones 173, 174 or 175, respectively\textsuperscript{74b}. Subsequent addition of mesitonitrile oxide to these solutions at −78 °C gave the corresponding oxathiazaplumboles 176–178, the [3+2]cycloadducts of plumbanethione 173–175, in moderate yields in each case (Scheme 54)\textsuperscript{74b,112}. Plumbanethiones 173 and 175 were also trapped with phenyl isothiocyanate to give the [2+2]cycloaddition products 179 and 181, respectively, though 174 did not afford such an adduct 180. The formation of new Pb-containing heterocycles 176–178, 179 and 181 is noteworthy as the first examples of the trapping of plumbanethiones. Observation of the color changes of the reaction solution suggests that plumbanethiones 173–175 thus formed are stable in solution, at least below −20 °C.

![Scheme 54](image)

Ttm group = 2,4,6-(CH\textsubscript{2}SMe\textsubscript{3})\textsubscript{3}C\textsubscript{6}H\textsubscript{2}

In order to elucidate the thermal stability of the plumbanethione 174, tetrathiaplumbolane 171 was desulfurized at higher temperature. Reaction of 171 with 3 equivalents of triphenylphosphine in toluene at 50 °C gave a deep red solution, from which plumbylene 182 was precipitated as pure deep red crystals (Scheme 55)\textsuperscript{113}. Besides 182, 1,3,2,4-dithiadiplumbetane 183 was obtained as another lead-containing major product. It should

![Scheme 55](image)
be noted that the final product 182 bears only Tbt groups, while 183 has only Tip groups, though the starting material 171 bears both Tbt and Tip groups on the lead atom.

The fact that the final products, 182 and 183, bear only Tbt and Tip groups, respectively, indicates the presence of some comproportionation process in their formation from 174. A plausible mechanism is shown in Scheme 56 for the formation of 182 and 183, though a detailed reaction mechanism is not clear at present\textsuperscript{113}. The tetrathiaplumbolane 171 is first desulfurized to provide plumbanethione 174, as has been seen in the desulfurization of 171 at low temperature. Plumbanethione 174 might undergo 1,2-aryl migration to give plumbylenes 184 and 185, which subsequently react to afford an arylsulfido bridged organolead heterocycle 186, since a less hindered arylthioplumbylene is known to have a tendency to oligomerize, forming a cyclic compound\textsuperscript{114a}. The retro [2+2]cycloaddition reaction of 186 affords 182 and 187. Dithiaadiplumbetane 183 may be obtained from the less crowded plumbylene 187.

X-ray crystallographic analysis reveals that plumbylene 182 exists as a monomer and there is no intermolecular interaction between the lead and sulfur atoms\textsuperscript{113a}, while other heteroatom-substituted plumbylenes so far known exist as the heteroatom-bridged cyclic oligomers\textsuperscript{114}.

\textit{b. Synthesis of plumbanethione by sulfurization of plumbylene.} In order to prove the 1,2-aryl migration process proposed for plumbanethione 174, the synthesis of plumbanethione 189 by sulfurization of a diarylplumbylene 188 with one atom equivalent of elemental sulfur at low temperature and the successive trapping reaction of 189 with mesitonitrile oxide were carried out (Scheme 57)\textsuperscript{74b}. The formation of cycloadduct 190 indicates the generation of intermediary plumbanethione 189. Furthermore, the fact that heating of a toluene solution of isolated plumbylene 188 with one atom equivalent of elemental sulfur at 50°C gave 182 clearly demonstrates the occurrence of 1,2-aryl migration in 189 (Scheme 57)\textsuperscript{74b}. The formation of 182 in this experiment is the first experimental demonstration that R(RS)Pb is more stable than R\textsubscript{2}Pb=S.

This interpretation of the experimental results was corroborated by \textit{ab initio} calculations on the relative stabilities of a series of double-bond compounds, [H\textsubscript{2}Pb=X], and
their plumbylene-type isomers, [trans-H-Pb-X-H] and [cis-H-Pb-X-H] (X = O, S, Se, and Te)\(^{74b}\). The results of the theoretical calculations and experiments for lead–chalcogen double-bond species are in sharp contrast to those of the other group 14 element analogues which do not isomerize to the divalent compounds\(^{88}\).

### D. Structures and Properties of Heavy Ketones

It is very important to reveal the structural features of heavy ketones and to make a systematic comparison with features of the carbonyl analogue such as the bond shortening and the trigonal planar geometry which result from the \(sp^2\) hybridization between the carbon and oxygen atoms. In the following sections, the experimentally and theoretically obtained features of heavy ketones, including the silicon-containing heavy ketones, are systematically compared.

#### 1. X-ray crystallographic analysis

First, a crystallographic analysis of the thermodynamically stabilized silanethione was established for the bulky silanethione 102b (Scheme 39). Although the Si–S bond [2.013(3) Å] in 102b is shorter than a typical Si–S single bond (2.13–2.16 Å)\(^{115}\), suggesting that it has a double-bond character to some extent, it is still 0.07 Å longer than the calculated value for the parent silanethione H\(_2\)Si=S. The Si–N distance (1.964 Å) in 102b, which is slightly longer than a Si–N \(\sigma\) bond (1.79 Å), supports a very strong coordination of the nitrogen atom of the dimethylaminomethyl group in 102b to the central silicon atom. Such intramolecular coordination in turn makes the silathiocarbonyl unit of 102b considerably deviant from the ideal trigonal planar geometry; the sum of the angles around the central silicon atom is 344.9°. The authors concluded that a resonance betaine structure contributes strongly to the electronic distribution of the internally coordinated silanethiones 102a,b.

Therefore, the elucidation of the intrinsic structural parameters of heavy ketones has to be done with kinetically stabilized systems. Most of the heavy ketones synthesized by taking advantage of the steric protection with the Tbt group have provided single crystals suitable for X-ray structural analysis. The results for silanethione 103, germanethione

*R The bond shortening (%) compared to the corresponding single bonds.

*Summation of the bond angles around the M atom.

112b, germaneselones 116, 125, germanetellones 118, 126 and stannaneselone 168 are summarized in Table 4.

The structural parameters of all heavy ketones examined show that they have an almost completely trigonal planar geometry and a distinct double-bond nature. The observed double-bond lengths and Δ₁/obs [bond shortening (%) compared to the corresponding single bonds] values are in good agreement with calculated values for H₂M=X₆b,88. These findings clearly indicate that heavy ketones have structural features similar to those of a ketone, although their double-bond character is lower than that of the corresponding carbon analogues as judged by their Δ₁/obs values.

It should be noted that all the M=X bond lengths observed are significantly shorter than those reported for the corresponding double-bond compounds stabilized by intramolecular coordination of heteroatoms. In other words, thermodynamically stabilized systems suffer from considerable electronic perturbation by heteroatom substituents.

Although some examples of thermodynamically stabilized double-bond systems between group 14 and 16 elements showed trigonal planar geometry due to their structural restriction, almost all of their bond lengths are longer than those of kinetically stabilized systems and of the values theoretically predicted116. These results clearly show that considerable electronic perturbation is inevitably involved in the thermodynamically stabilized systems.

2. NMR spectra

As in the case of ¹³C NMR, low-field chemical shifts are characteristic of sp²-hybridized nuclei also in the heavy ketones. For example, the ²⁹Si chemical shifts of silanethione 103 and silaneselone [Tbt(Dip)Si=Se (191)]⁸⁸,¹¹⁷ are 167 and 174 ppm, respectively. Silanetellone [Tbt(Dip)Si=Te (192)]⁸⁸,¹¹⁷ also shows its ²⁹Si NMR signal at 171 ppm. In contrast, the ²⁹Si NMR signal of Corriu’s compound 102a (X=S) appears at 22.3 ppm⁸⁷, indicating the high sp³ nature of the silicon centers in 102a. In the cases of the above-mentioned silaneselone and silanetellone, the characteristic low-field ⁷⁷Se and ¹²⁵Te chemical shifts of 191 (δSe = 635) and 192 (δTe = 731) are also indicative of their sp²-hybridized chalcogen atoms.

Similarly, stannanethione 166 and stannaneselone 168 kinetically stabilized by Tbt and Ditp groups have ¹¹⁹Sn chemical shifts of 531 and 440 ppm, respectively. Kuchta and Parkin have reported the synthesis of stable terminal chalcogenido complexes of tin 193 (Scheme 58), and the chemical shifts for the central tin atom appears at a much higher field, i.e. −303 ppm (193a, X=S) and −444 ppm (193b, X=Se)⁹¹. This clearly shows that the thermodynamically stabilized tin–chalcogen double bonds in 193 (X=S, Se) are electronically perturbed to a great extent.
On the other hand, such information is not available for germanium-containing heavy ketones because of the difficulty in observing Ge NMR spectra, but the low-field shifted $^{77}$Se and $^{125}$Te NMR signals of germaneselenones [δSe = 941 (for 116) and 872 (for 125)]$^{95,97}$ and germanetellones [δTe = 1143 (for 118) and 1009 (for 126)]$^{99,103}$ are in agreement with the $sp^2$-hybridization of these elements as in the cases of silaneselonel 191 and silanetellone 192.

3. UV-vis spectra

Table 5 lists characteristic visible absorptions observed for the heavy ketones kinetically stabilized by the Tbt group.

It is known that the $n$–$\pi^*$ absorptions of a series of $R_2C=X$ ($X = O, S, Se, Te$) compounds undergo a systematic red shift on going down the Periodic Table.$^{84}$ A similar tendency is observed also for the Si, Ge and Sn series of Tbt(R)Si=$X$ ($X = S, Se$), Tbt(R)Ge=$X$ ($X = S, Se, Te$) and Tbt(R)Sn=$X$ ($X = S, Se$). In contrast, one can see a very interesting trend in the absorption maxima of two series Tbt(R)M=S and

| TABLE 5. Electronic spectra ($n$–$\pi^*$) of doubly bonded compounds between group 14 elements and chalcogens |

Tbt(R)M=Se (M = C, Si, Ge, Sn). In both series the $\lambda_{\text{max}}$ values are greatly blue-shifted on going from carbon to silicon congeners, whereas the $\lambda_{\text{max}}$ values of silicon, germanium and tin congeners are red-shifted with increasing atomic number of the group 14 elements. This trend is also found in the calculated values for H2M=S (M = C, Si, Ge, Sn)\(^6,88\). Since the calculated $\Delta\epsilon_{n\pi^*}$ values increase continuously from H2Sn=S to H2C=S, a long wavelength absorption for H2C=S (and hence for TbtCH=S\(^69\)) most likely results from a large repulsion integral ($J_{n\pi^*}$) for the carbon–sulfur double bond, as in the case of H2C=O vs H2Si=O\(^118\).

4. Raman spectra

The stretching vibrations of the M=X bond were measured by Raman spectra for silanethione \(^103\) (724 cm\(^{-1}\)), germanethiones \(^112\) (521 cm\(^{-1}\)) and \(^124\) (512 cm\(^{-1}\)), and germanetellones \(^118\) (381 cm\(^{-1}\)) and \(^126\) (386 cm\(^{-1}\)). These values are in good agreement with those calculated for H2M=X compounds \([723 (\text{Si}=\text{S}), 553 (\text{Ge}=\text{S}) \text{ and } 387 (\text{Ge}=\text{Te}) \text{ cm}^{-1}\], respectively\(^6,88\). It is noteworthy that the observed value for Tbt(Tip)Ge=S \(^112\) is very close to that observed by IR spectroscopy for Me2Ge=S \(^119\) in a argon matrix at 17–18 K\(^119\), indicating similarity in the nature of the bond of both germanethiones in spite of the great difference in the size and nature of the substituents.

E. Reactivities of Heavy Ketones

As mentioned in the previous sections, heavy ketones undergo ready head-to-tail dimerization (or oligomerization) when the steric protecting groups on the group 14 element are not bulky enough to suppress their high reactivity. Indeed, Tbt(Mes)M=X (M = Si, Ge; X = S, Se) cannot be isolated at an ambient temperature and instead the dimerization products are obtained. In the cases of tin-containing heavy ketones, the dimerization reactions are much easier than in the lighter group 14 element congeners, and only the combination of Tbt and Ditp groups can stabilize the long and reactive tin–chalcogen double bonds (\textit{vide supra}).

Although the high reactivity of metal–chalcogen double bonds of isolated heavy ketones is somewhat suppressed by the steric protecting groups, Tbt-substituted heavy ketones allow the examination of their intermolecular reactions with relatively small substrates. The most important feature in the reactivity of a carbonyl functionality is the reversibility in the reactions across its carbon–oxygen double bond (via the addition–elimination mechanism via a tetracoordinate intermediate) as is observed, for example, in reactions with water and alcohols. The energetic basis of this reversibility is that there is very little difference in the $\sigma$ and $\pi$ bond energies of the C=O bond (Table 3). In contrast, an addition reaction involving a heavy ketone is highly exothermic and hence essentially irreversible because of the much smaller $\pi$ bond energy than the corresponding $\sigma$ bond energy of these species.

All heavy ketones kinetically stabilized by a Tbt group react with water and methanol almost instantaneously to give tetracoordinate adducts (Scheme 59). They also undergo cycloadditions with unsaturated systems such as phenyl isothiocyanate, mesitonitrile oxide and 2,3-dimethyl-1,3-butadiene to give the corresponding [2+2]-, [2+3]- and [2+4]cycloadducts, respectively (Scheme 59). The former two reactions proceed at room temperature, while the reaction with the diene takes place at higher temperature, with the lighter homologues requiring more severe conditions.

Reaction of \(^112\) with methyllithium followed by alkylation with methyl iodide gives a germophilic product \(^194\). The [2+4]cycloaddition of \(^112\) with 2-methyl-1,3-pentadiene affords \(^195\) regioselectively. When a hexane solution of \(^195\) is heated at 140 °C in a sealed tube in the presence of excess 2,3-dimethyl-1,3-butadiene, a dimethylbutadiene adduct \(^196\)
is obtained in a high yield, indicating that the Diels–Alder reaction of germanethione 112b with a diene is reversible, and hence that a diene adduct such as 195 or 196 can be a good precursor of germanethione 112b (Scheme 60). Similar reactivity was observed for germaneselone 116, and the retrocycloaddition of 197 (shown by the formation of 198) takes place at a much lower temperature (50°C) than that for 195, suggesting a weaker C–Se bond than a C–S bond (Scheme 60).
In contrast to the considerable thermal stability of the isolated heavy ketones of silicon, germanium and tin, a plumbanethione behaves differently. When stable plumbylene $\text{Tbt}_2\text{Pb}$ was sulfurized by 1 molar equivalent of elemental sulfur at $50^°\text{C}$, the heteroleptic plumbylene $\text{TbtPbSTbt} (182)$ was obtained (Scheme 57) instead of plumbanethione $\text{Tbt}_2\text{Pb}=\text{S} (189)$, which is an expected product in view of the reactivity observed for divalent species of silicon, germanium and tin (vide supra). The formation of 182 is most reasonably explained in terms of 1,2-migration of the Tbt group in the intermediate plumbanethione 189, and this observation is supporting evidence for the 1,2-aryl migration in plumbanethione 174 proposed in the reaction shown in Scheme 56. This unique 1,2-aryl migration in a plumbanethione is in keeping with a theoretical calculation which reveals that plumbylene HPb(SH) is about 39 kcal mol$^{-1}$ more stable than plumbanethione $\text{H}_2\text{Pb}=\text{S}$.74b.

IV. HEAVIER CONGENERS OF ALLENES

a. Silaallene. As can be seen in the previous sections, a variety of heavier element analogues of alkenes and ketones have been isolated by taking advantage of kinetic stabilization using bulky substituents and their structures have been characterized by X-ray crystallographic analysis. Also, there have been reported some stable examples of heavier congeners of imines such as silaneimines, $\text{R}_2\text{Si}=\text{NR}_1$.3 and germaneimines, $\text{R}_2\text{Ge}=\text{NR}_1$.121. On the other hand, the chemistry of cumulative double-bond compounds of heavier group 14 elements is less explored. In 1993, the first stable silacumulene, 1-silaallene 200, was synthesized by the reaction of well-designed alkynyl fluorosilane 199 with $\text{t}$-butyllithium by West and coworkers (Scheme 61)8a. Silaallene 200 was isolated as stable crystals and characterized by X-ray structural analysis, but very little is known about its reactivity8.

b. Germaallenes. Regarding the cumulene-type compounds containing a germanium atom, germaphosphaallene 202 was synthesized by Escudié and coworkers in 1996 using the reduction of (fluorogermyl)bromophosphaalkene 201 (Scheme 62)122. Although the generation of 202 was confirmed by $^{13}\text{C}$ and $^{31}\text{P}$ NMR at $-40^°\text{C}$, 202 dimerized at room temperature to afford two types of dimers, i.e. 203 and 204 (Scheme 62)122. This result shows that the combinations of the substituents on the germanium and phosphorous atoms were not bulky enough to prevent dimerization of 202.

In 1997, Tokitoh, Okazaki and coworkers reported evidence for the generation of a kinetically stabilized 1-germaallene 207. It was synthesized by two different synthetic approaches as shown in Scheme 63. One is the dechalcogenation reaction of the corresponding alkylidenetelluragermirane 205 with a phosphine reagent, and the other is the reduction of (1-chlorovinyl)chlorogermane 206 with $\text{t}$-butyllithium.

Both reactions afforded an identical product as judged by its NMR spectrum, and 1-germaallene 207 was found to be marginally stable in solution, showing the characteristic low-field $^{13}\text{C}$ NMR chemical shift for its central $sp$ carbon atom ($\delta_c = 243.6$ in C$_6$D$_6$). The down-field shift for the central $sp$ carbon has been also observed for 1-silaallene 200 ($\delta_c = 226$)8 and germaphosphaallene 202 ($\delta_c = 281$)122. Although 207 can be trapped with methanol, mesitonitrile oxide and elemental sulfur to give the corresponding adducts 208–210, it slowly undergoes an intramolecular cyclization in solution at room temperature to give compound 211 (Scheme 64)25,123. Concentration and isolation of 207 as crystals at low temperature has failed, and no crystallographic information has been obtained for 207 so far.

In 1998, West and coworkers succeeded in the synthesis and isolation of 1-germaallene 212, the first example of a stable 1-germaallene either in solution or in the solid state.
13. Multiply bonded germanium, tin and lead compounds

(Scheme 65)\textsuperscript{124}. \textbf{212} was stable in ether solution up to 0 °C but is completely decomposed after 15 h at 25 °C, whereas it remained unchanged in toluene up to 135 °C. Gemallene \textbf{212} was isolated by crystallization from ether at −20 °C as colorless crystals, which showed a low-field \textsuperscript{13}C NMR signal at 235.1 ppm in toluene-$d_8$ as in the case of \textbf{207}\textsuperscript{124}.

A crystallographic analysis of \textbf{212} had revealed the structural parameters for this unique cumulative bonding\textsuperscript{124}. The G=C bond length is 1.783(2) Å and the Ge=C=C unit is not linear, having a bending angle of 159.2°. The sum of the bond angles at Ge (348.4°) indicates a strong pyramidalization around the Ge center.

c. Tristannaallene. Quite recently, Wiberg and coworkers reported the first example of 1,2,3-tristannaallene \textbf{214} by taking advantage of the tri-$t$-butylsilyl (supersilyl) group\textsuperscript{125}. It was synthesized by the reaction of diaminostannylene \textbf{213} with supersilyl sodium (Scheme 66).
At the first stage below $-25 \, ^\circ\mathrm{C}$ (in pentane/C$_6$D$_6$) this reaction yields the tristannaallene 214, but it rearranges at $25 \, ^\circ\mathrm{C}$ to the isomeric cyclotristannene 215. The formation of 214 can be interpreted in terms of an initial formation of disupersilylstannylene 216 (Scheme 67)$^{125}$. 

\[ \text{Mes}^* = 2,4,6-(t-Bu)_3C_6H_2 \]

SCHEME 62

SCHEME 63
Although several examples of heavy allenes have been synthesized as stable compounds, most of them are isolated as marginally stable species at room temperature. Further systematic progress is necessary in order to elucidate the intrinsic properties of these interesting doubly bonded systems of heavier group 14 elements.
This chapter outlines the recent progress in the chemistry of multiply bonded species of Ge, Sn, and Pb. As can be concluded from this chapter and related recent reviews which deal with the chemistry of this family of compounds which are stable at room temperature, the field of low-coordinated species of heavier group 14 elements has matured considerably in recent years.

For example, we can now make a systematic comparison for heavy ketones through silicon to lead. However, heavy ketones containing an oxygen atom are still elusive species and neither their isolation nor spectroscopic detection has been achieved so far probably due to their extremely high reactivity caused by their highly polarized structure. The most fascinating and challenging target molecules in this area should be the stable oxygen-containing heavy ketones (Scheme 68).

As for the multiply bonded systems of heavier group 14 elements, all the homonuclear double bonds were successfully isolated and characterized by the end of the last century. However, the chemistry of heteronuclear double bonds and those of conjugated systems are still in growth. The synthesis and isolation of unprecedented cumulative systems such as (Scheme 68) and aromatic systems containing Ge, Sn and Pb atoms, e.g. (219–222) (Scheme 68), will also be within the range of this future chemistry. Likewise, the synthesis and isolation of the triply bonded systems (Scheme 68) should be one of the most challenging projects in this field.

SCHEME 66

SCHEME 67

V. OUTLOOK AND FUTURE
As can be seen from this chapter, kinetic stabilization has been used as a much superior method to thermodynamic stabilization in order to elucidate the intrinsic nature of the chemical bonding containing low-coordinated heavier group 14 elements. However, it might be useful to combine the two types of different stabilization methods for the synthesis and isolation of much more reactive systems as mentioned above.

Elucidation of the intrinsic properties of unprecedented chemical bondings of heavier group 14 elements and their systematic comparison will be of great importance in efforts to extend the conventional organic chemistry to that of the whole main group elements.

I. INTRODUCTION

The chemistry of stable, small cyclic compounds consisting of heavy Group 14 elements (i.e. Si, Ge and Sn) has a relatively short but very impressive history. In contrast to their transient congeners, which were proposed a long time ago, the stable three-membered
ring compounds were reported for the first time only in 1982 by Masamune’s group. After the synthesis of the first representatives of cyclotrismetallanes, cyclotrigermenes and cyclotristarstananes, the chemistry of such molecules has been greatly developed during the past two decades. These compounds, similar to their carbon analogue — cyclopropane, were found to be very reactive because of their significant ring strain and the weakness of the endocyclic metal–metal bonds. The most fundamental discovery of their reactivity was the cycloelimination reaction to produce two kinds of key reactive species — heavy carbene analogues and dimetallaalkenes (dimetallenes). This is now a well-established way to generate such reactive intermediates. Heterocyclotrismetallanes consisting of different heavier Group 14 elements can be easily imagined as a convenient source for the preparation of heterodimetallenes, which can possess unusual structural and chemical properties. Nevertheless, until now there have been only a few examples of such ‘mixed’ cyclotrismetallanes, which can be explained by the difficulties in their preparation relative to their ‘homo’ analogues.

Cyclotrimetallenes, compounds that combine the cyclotrismetallane skeleton and an endocyclic metal–metal double bond in one molecule, have not been synthesized until quite recently because of the great ring strain and high reactivity of the metal–metal double bond. Nevertheless, employment of bulky silyl substituents, which sterically protect the molecule and decrease the ring strain, makes possible the successful preparation of the cyclotrimetallenes. After the first report of the synthesis of cyclotrimetallenes, there was an explosive growth in the development of their chemistry. However, even now there is a very limited number of methods for their synthesis, which are not general and usually more complicated than in the case of cyclotrismetallanes. The reactivity of cyclotrimetallenes, which combine the chemical properties of both cyclotrismetallanes and dimetallenes, was found to be very rich. Various addition and cycloaddition reactions across the metal–metal double bond give access to new cyclic and bicyclic compounds, whereas insertion reactions into the three-membered ring produce ring enlargement products. In the present review, we will concentrate only on the very recent developments in the chemistry of cyclotrimetallenes (unsaturated three-membered ring systems) of heavier Group 14 elements. Special attention will be paid to the chemistry of the cyclotrigermenium cation — the free germyl cation with a $2\pi$-electron system. The chemistry of cyclotrismetallanes, that is, their saturated analogues, will not be considered in this article, since it has already been described in previous reviews.

II. CYCLOTRIMETALLENES — UNSATURATED THREE-MEMBERED RINGS OF HEAVIER GROUP 14 ELEMENTS

A. Cyclotrisilenes

The synthesis of the first cyclotrisilenes has required a longer time than for the cyclotrigermenes due to the lack of suitable stable silylenes, in contrast, for example, to the well-known dichlorogermylene–dioxane complex. The preliminary preparation of the silylene precursors, which can generate silylenes $\textit{in situ}$, was necessary for the successful synthesis of cyclotrisilenes. Until now, only two examples of cyclotrisilenes have been reported in the literature, of which only one was structurally characterized.

These first reports on the preparation of the stable cyclotrisilenes appeared in 1999, when two groups independently published consecutive papers on the cyclotrisilenes bearing different substituents. Cyclotrisilene, which was prepared in Kira’s group, has three tert-butyldimethylsilyl substituents and a bulky tris(tert-butyldimethylsilyl)silyl group attached to one unsaturated silicon atom. This compound was obtained by the reaction...
of \( R_3\text{Si}\text{SiBr}_2\text{Cl} \) (\( R = \text{SiMe}_2\text{Bu-}t \)) with potassium graphite in THF at \(-78^\circ\text{C} \) in 11\% yield as dark red crystals (Scheme 1). The existence of the doubly-bonded silicon atoms was determined from the \(^{29}\text{Si} \) NMR spectrum, which showed two down-field signals at 81.9 and 99.8 ppm. These are significantly shifted up-field relative to those for the acyclic tetrasyldisilenes (142–154 ppm)\(^{26} \). The structure of 1 was proved by reaction with \( \text{CCl}_4 \), for which the structure of the product 2 was established by X-ray crystallography. It is interesting that the final product of the reduction of \( R_3\text{Si}\text{SiBr}_2\text{Cl} \) depends strongly on the reducing reagent. Thus, treatment of \( R_3\text{Si}\text{SiBr}_2\text{Cl} \) with sodium in toluene at room temperature gave the cyclotetrasilene 3\(^{27} \) in 64\% yield without any formation of 1.

The second example of a cyclotrisilene was reported by Sekiguchi’s group\(^{15} \). This compound was prepared by the reductive coupling of \( \text{R}_2\text{SiBr}_2 \) and \( \text{RSiBr}_3 \) [\( R = \text{SiMe}_2\text{Bu-}t \)] \(_2 \) with sodium in toluene at room temperature (Scheme 2). Cyclotrisilene 4 was isolated as red-orange crystals in 9\% yield. The \(^{29}\text{Si} \) NMR spectrum of 4 showed a down-field signal at 97.7 ppm, which is attributable to the unsaturated silicon atoms, and an up-field signal at \(-127.3 \) ppm, which is typical for a saturated silicon atom in a three-membered ring system.

Cyclotrisilene 4 has a symmetrical structure (\( C_{2v} \) symmetry), which allowed the growth of a single crystal and the determination of its crystal structure (Figure 1). X-ray analysis has revealed an almost isosceles triangle with bond angles of 62.8(1), 63.3(1) and 53.9(1)\(^{\circ} \). The geometry around the \( \text{Si} = \text{Si} \) double bond is not planar, but \( \text{trans} \)-bent with a torsion angle \( \text{Si}_4 - \text{Si}_1 - \text{Si}_2 - \text{Si}_5 \) of 31.9(2)\(^{\circ} \). The \( \text{Si} = \text{Si} \) double bond length in 4 is 2.138(2) \( \text{Å} \), which was recognized as one of the shortest distances among the \( \text{Si} = \text{Si} \) double bond
lengths reported thus far. The UV-Vis spectrum of 4 showed four bands with maxima at 223 (ε = 7490), 259 (3610), 297 (1490) and 466 nm (440).

B. Cyclotrimerenenes

Historically, cyclotrimerenenes were the first cyclotrimetallenes of Group 14 elements to be prepared. At present, six cyclotrimerenenes have been described in the scientific literature, and four of them have been structurally characterized. In 1995, Sekiguchi and coworkers reported the unexpected formation of an unsaturated three-membered ring system consisting of Ge atoms by the reaction of dichlorogermyle–dioxane complex with tris(tert-butyl)silyl sodium or tris(tert-butyl)gernyl lithium at −70 °C in THF (Scheme 3). Cyclotrimerenenes 5 and 6 were isolated as dark-red crystals by gel-permeation chromatography. The NMR spectra of cyclotrimerenenes are very simple, because of their symmetrical structures, showing only two sets of signals in 1H, 13C and 29Si NMR spectra. The structures of both 5 and 6 were confirmed by X-ray crystallography, which showed the completely planar geometry around the Ge=Ge double bond.
bond with a Ge=Ge double bond length of 2.239(4) Å (for 5 see Figure 2). Such planarity is somewhat unusual, since all digermenes reported before have a trans-bent configuration of the Ge=Ge double bond with folding angles of 12–36°.29–32.

The mechanism of the formation of a three-membered unsaturated ring was clarified later, when this reaction was reexamined by the same authors in detail.18 They found that the reaction of dichlorogermylene–dioxane complex with one equivalent of t-Bu₃SiNa in THF at −78 °C led to the formation of cis,trans-1,2,3-trichloro-1,2,3-tris(tri-tert-butylsilyl)cyclotrigermene 7 in 98% yield (Scheme 4). The cis,trans conformation of 7 was established by NMR spectroscopy and X-ray analysis (Figure 3). Treatment of 7 with two equivalents of t-Bu₃SiNa in THF at −78 °C cleanly produced cyclotrigermene 5 (Scheme 4), which gives evidence that 7 is a precursor for 5.

Monitoring of the reaction by 29Si NMR allowed the detection of the reaction intermediates, which cannot be isolated, but were evidenced by trapping reactions (Scheme 5 and Figure 4). The first intermediate — digermenoid 8 (two signals at 21.9 and 23.7 ppm in the 29Si NMR spectrum) — was quenched with hydrochloric acid at −78 °C with the formation of a protonated product 9. With iodomethane, a methylated product 10 was quantitatively obtained. Above −8 °C the digermenoid 8 undergoes selective β-elimination to give another intermediate — digermene t-Bu₃Si(Cl)Ge=Ge(Cl)Si(Bu-t)3 11, which cannot be seen in the 29Si NMR spectrum, but can be trapped with dienes (Scheme 5). With both isoprene and 2,3-dimethyl-1,3-butadiene the corresponding cyclohexene derivatives 12 and 13 were obtained, whereas germacyclopentene derivatives were not found, which
$t$-Bu$_3$SiNa + GeCl$_2$·dioxane $\xrightarrow{\text{THF} \ -78^\circ \text{C} \to \text{RT}}$ $t$-Bu$_3$Si $\cdot$ Ge$\equiv$Ge $\cdot$ Si(Bu-t)$_3$

$\xrightarrow{-78^\circ \text{C} \to \text{RT}}$ $t$-Bu$_3$SiNa

$t$-Bu$_3$SiCl + $t$-Bu$_3$Si $\cdot$ Ge$\equiv$Ge $\cdot$ Si(Bu-t)$_3$

SCHEME 4

FIGURE 3. ORTEP drawing of cyclotrimerene 7. Reprinted with permission from Reference 18. Copyright 2000 American Chemical Society
indicates that α-elimination to generate a germylene species is not involved in the reaction pathway. Thus, the reaction of GeCl₂•dioxane with t-Bu₃SiNa can be explained by the following mechanism. First, insertion of dichlorogermylene into the Si−Na bond occurred to form the germlenoid t-Bu₃SiGeCl₂Na, which undergoes self-condensation to afford digermnenoid 8, stable at low temperature. Second, above −8 °C thermal decomposition of 8 gives digermene 11 as an intermediate. And finally, this digermene reacts with digermnenoid 8, followed by cyclization with formation of trichlorocyclotrigermene 7 and germlyenoid 14. The resulting 7 then transforms into the final cyclotrigermene 5.

Other examples of cyclotrigermenes were synthesized in a different way by Sekiguchi and coworkers, taking advantage of the previously prepared cyclotrigrermenium cation, whose synthesis will be described later (see Section II.E.3). Thus, unsymmetrically substituted cyclotrigrermenenes were prepared by the reactions of tris(tri-tert-butylsilyl)cyclotrigermenium tetrakis[3,5-bis(trifluoromethyl)phenyl]borate (TFPB⁻) 15 with the appropriate nucleophiles (Scheme 6)¹⁷. This method seems to be a convenient route for the preparation of new cyclotrigrermenenes. Thus, reaction of 15 with t-Bu₃SiNa, t-Bu₃GeNa, (Me₃Si)₃SiLi•3THF, (Me₃Si)₃GeLi•3THF or MesLi at −78 °C quickly produced the corresponding unsymmetrically substituted cyclotrigrermenenes 5, 16–19 in high yields. It was quite interesting to know that the geometry around the Ge=Ge
FIGURE 4. Reaction intermediate in the reaction of GeCl₂-dioxane with t-Bu₃SiNa in THF-d₈ monitored by ²⁹Si NMR spectroscopy: formation of digermenoid 8 and its thermal transformation to a cyclotrigermene 7. Reprinted with permission from Reference 18. Copyright 2000 American Chemical Society.

**Scheme 6**

Double bond in 17 is not trans-bent, which is the general case for the dimetallenes of Group 14²⁹−³², but cis-bent with folding angles of 12.5° for the Ge3 atom and 4.4° for the Ge2 atom (Figure 5). The Ge=Ge double bond length is 2.264 Å, which lies in the normal region. Such an unusual cis-bent configuration was well reproduced by *ab initio* calculations: the cis folding angles are 8.8° and 5.8° for Ge3 and Ge2 atoms, respectively. No energy minimum was found for the trans-bent form. Therefore, the cis-bent geometry is caused by both steric and electronic effects of the substituents at the endocyclic saturated...
germanium atom, but not by a crystal packing force. As was mentioned above, usually the digermenes exhibit a trans-bent configuration, which becomes less pronounced upon the introduction of electropositive substituents, such as $R_3Si$ groups. In the case of cyclotrigermene 17, using such electropositive and bulky silyl substituents caused the formation of a Ge=Ge double bond with an unprecedented cis-bent geometry.

**C. Cyclotristannene**

Until now, there was only one example of a cyclotristannene—tetrakis(tert-butyldimethylsilyl)cyclotristannene 20 reported by Wiberg and coworkers in 1999. The title compound 20 was prepared by the reaction of $t$-Bu$_3$SiNa with stable stannylenes $Sn[SiMe_3]_2$ or $Sn(OBu-t)_2$ in pentane at room temperature (Scheme 7). It was isolated as dark, red-brown crystals in 27% yield. In agreement with the symmetrical structure of the molecule, 20 exhibits only two sets of signals in the $^1H$, $^{13}C$ and $^{29}Si$ NMR spectra. The most important and informative was the $^{119}Sn$ NMR spectrum, which showed both up-field (−694 ppm) and down-field (412 ppm) resonances. The last one is typical for the three-coordinated doubly-bonded tin atoms, whereas the first one can be assigned to an endocyclic Sn atom in a three-membered ring system.

The structure of 20 was determined by X-ray analysis, which showed an almost planar environment around the Sn=Sn double bond. All the previously reported distannenes have a trans-bent configuration around the Sn=Sn double bond. The Sn=Sn double bond

\[ \text{Sn}[\text{SiMe}_3]_2 + t\text{-Bu}_3\text{SiNa}/\text{pentane} \rightarrow \text{R}_2\text{Sn} \equiv \equiv \text{SnR}_2 \]  
(21) $R = \text{Si(Bu-t)}_3$

\[ \text{Sn(OBu-t)}_2 + t\text{-Bu}_3\text{SiNa}/\text{pentane} \rightarrow \text{R} \equiv \equiv \text{R} \]  
(20) $R = \text{Si(Bu-t)}_3$

**SCHEME 7**
length was only 2.59 Å — the shortest among all distannenes structurally characterized so far.\textsuperscript{34–38}

One of the most important findings of the reaction was a discovery of the intermediately formed tristannaallene 21, which is not very thermally stable and at room temperature rearranges to the isomeric cyclotristannene 20 (Scheme 7). Such rearrangement apparently implies the migration of one silyl substituent followed by cyclization. Nevertheless, it was possible to isolate compound 21 in 20% yield as dark-blue crystals, which were highly air and moisture sensitive and isomerized slowly at room temperature to form cyclotristannene 20. Such isomerization takes place by a first-order reaction with a half-life of 9.8 h at 25°C. The structure of the tristannaallene 21 was supported by \textsuperscript{119}Sn and \textsuperscript{29}Si NMR spectra. In the \textsuperscript{119}Sn NMR spectrum of 21, two down-field signals at 503 and 2233 ppm were observed with an intensity ratio 2 : 1. The first one was attributed to the terminal Sn atoms in an allene unit, which is in agreement with the only reported distannene compound that is stable at room temperature in solution, \((2,4,6-(i-Pr)\textsubscript{3}C\textsubscript{6}H\textsubscript{2})\textsubscript{2}Sn=Sn(2,4,6-(Pr-\textsubscript{i}\textsubscript{3}C\textsubscript{6}H\textsubscript{2})\textsubscript{2})\) (\(\delta = 427.3\)).\textsuperscript{34} The central allenic Sn atom, which formally has sp type hybridization, resonates at a much lower field (2233 ppm), which is the usual shift for the stannylenes\textsuperscript{39–41}. Such similarity suggests that the central tin atom in 21 has a considerable stannylenene character, therefore the bonding situation in 21 is best described by the resonance formula shown in Scheme 8. The \textsuperscript{29}Si NMR spectrum of 21 showed only one signal at 77.3 ppm.

The crystal structure of 21 was finally confirmed by X-ray analysis, which showed an unexpectedly short Sn=Sn double bond length of 2.68 Å (Figure 6). This bond length is the shortest among all distannenes reported thus far (2.77–2.91 Å)\textsuperscript{34–38}, although it is longer than that in 20 (2.59 Å). Another important feature of the allene 21 is a bent, rather
than linear, Sn₃ chain. Such a phenomenon was explained by the large contribution of the resonance formulae \[ R₂Sn ↔ SnR₂ \] in the structure of 21 rather than the real allenic structure. The geometry around the terminal tin atoms in the Sn₃ chain in 21 is not planar, as in the case of the corresponding carbon atoms in allenes. The (t-Bu₂Si)₂Sn groups in 21 adopt, similar to the R₂C groups in allenes, a gauche configuration; thus the four t-Bu₂Si groups mask the Sn₃ chain almost completely to prevent intermolecular reactions between the Sn₃ units.

D. ‘Mixed’ Cyclotrimetallenes

It was expected that ‘mixed’ cyclotrimetallenes—that is, the three-membered ring compounds consisting of different Group 14 elements—would possess some interesting and unusual properties that may distinguish them from their homonuclear analogues (cyclotrisilenes, cyclotrigermenes and cyclotristannenes). First, such interest concerned the structural characteristics and the specific reactivity of the ‘mixed’ cyclotrimetallenes. The synthesis of the title compounds was not obvious, and until now only two examples of such molecules have been reported. In 2000, Sekiguchi and coworkers reported the first representatives of such unsaturated molecules: 1- and 2-disilagermiresnes 22 and 23. 1-Disilagermirene 22 was prepared by the Wurtz-type reductive coupling reaction of R₂GeCl₂ and RSiBr₃ \[ R = SiMe(t-Bu)_2 \] with sodium in toluene (Scheme 9). Compound 22 was isolated as hexagonal ruby crystals in 40% yield and appeared to be highly air and moisture sensitive. The \(^1\text{H}\) and \(^13\text{C}\) NMR spectra corresponded well with a symmetrical structure for 22, showing only two sets of signals for methyl- and tert-butyl groups, whereas the \(^29\text{Si}\) NMR spectrum displayed three resonances at 18.7, 25.6 and 107.8 ppm, of which the first two belong to the silyl substituents, and the last one is characteristic of the Si=Si double bond.

![Scheme 9](image)

The molecular structure of 1-disilagermirene 22 was determined by X-ray crystallography (Figure 7). The three-membered ring represents an almost isosceles triangle with bond angles of 52.71(3), 63.76(3) and 63.53(3)°. The silicon–silicon double bond length of 22 is 2.146(1) Å, which is rather short compared with other Si=Si double bond lengths reported so far (2.138–2.289 Å). The average bond length between Ge and the two Si atoms in the ring is 2.417 Å, which is intermediate between the endocyclic Ge–Ge bond length of 2.522 (4) in cyclotrigermene and the Si–Si bond length of 2.358 (3) Å in cyclotrisilene. The geometry around the Si=Si bond is not planar, but trans-bent with a torsional angle Si3–Si1–Si2–Si4 of 37.0(2)°. One of the possible reasons for such twisting of the Si=Si double bond may be the eclipsed conformation of the two t-Bu₂MeSi substituents connected to the unsaturated silicon atoms.

Under photolysis of the benzene solution of 22 with a high pressure Hg lamp (λ > 300 nm) for 4 h, a migration of the silyl substituent with the formation of an endocyclic Si=Ge double bond system takes place (Scheme 10). The reaction proceeds quite cleanly.
and the 2-disilagermirene 23 was formed almost quantitatively. Compound 23 represents the first example of a stable germasilene reported to date, since the only previously reported example by Baines and Cooke, tetramesitylgermasilene, is unstable and can survive only at a low temperature.\(^{43}\)

\[ \text{Si}(6) \quad \text{Si}(5) \quad \text{Ge}(1) \quad \text{Si}(1) \quad \text{Si}(2) \quad \text{Si}(3) \]

**FIGURE 7.** ORTEP drawing of 1-disilagermirene 22. Reprinted with permission from Reference 19. Copyright 2000 American Chemical Society.

**SCHEME 10**
The 2-disilagermirene $^{23}$ was isolated from hexane solution as scarlet plate crystals and appeared to be extremely thermally stable with a melting point of 194–196 °C. The $^1$H and $^{13}$C NMR spectra of $^{23}$ are more complicated than those of $^{22}$, because the 2-disilagermirene $^{23}$ has lost the C$_{2v}$ symmetry of the 1-disilagermirene $^{22}$. Thus, the $^1$H NMR spectrum of $^{23}$ showed three resonances for three types of methyl groups and four resonances for non-equivalent tert-butyl groups, whereas the $^{13}$C NMR spectrum showed three sets of signals both for methyl and tert-butyl groups. The $^{29}$Si NMR spectrum showed five signals, of which three belong to the silyl substituents, 39.5, 27.8 and 6.9; the endocyclic doubly-bonded Si atom exhibits a down-field resonance at 106.7 and the endocyclic saturated Si atom has an up-field resonance at −120.1 ppm.

The molecular structure of 2-disilagermirene $^{23}$ was established by X-ray crystallography, which revealed a triangular structure composed of one saturated silicon atom, one unsaturated silicon atom and one unsaturated germanium atom. Although the accurate determination of bond lengths and angles in the three-membered ring was impossible because of significant disorder in the positions of doubly bonded Si and Ge atoms, it was possible to determine the geometry around the Si=Ge double bond, which also has a trans-bent configuration with a torsional angle of 40.3(5)°.

The isomerization of $^{22}$ to $^{23}$ can also be performed under thermal conditions. Thus, thermolysis of a solution of $^{22}$ in mesitylene at 120 °C cleanly produced 2-disilagermirene $^{23}$ in one day. Thermolysis can also be performed in benzene solution in a temperature interval from 80 to 100 °C, but it requires a longer reaction time, about 4 days. Thermal reaction of $^{22}$ produced an equilibrium mixture of $^{22}$ (2%) and $^{23}$ (98%), from which it was estimated that $^{23}$ is more stable than $^{22}$ by ca 3 kcal mol$^{-1}$. Thermolysis of $^{22}$ without solvent at 215 °C cleanly produces 2-disilagermirene $^{23}$ quantitatively in 20 minutes without any side products.

Ab initio calculations on the model H$_3$Si-substituted 1-disilagermirene $^{24}$ and 2-disilagermirene $^{25}$ at the MP2/DZd and B3LYP/DZd levels show the Si=Si double bond length in $^{24}$ to be 2.105 Å (MP2) and 2.107 Å (B3LYP), which agree well with the experimental value of 2.146 Å. The Si=Ge double bond length in $^{25}$ was predicted to be 2.180 Å (MP2) and 2.178 Å (B3LYP). It was also found that $^{25}$ is more stable than $^{24}$ by 3.9 (MP2) and 2.3 (B3LYP) kcal mol$^{-1}$. These values are in good agreement with the experimentally estimated value of ca 3 kcal mol$^{-1}$.

E. Reactivity of Cyclotrimetallenes

The reactivity of the three-membered unsaturated rings of heavier Group 14 elements is still largely unknown, although one can easily expect them to have very interesting properties arising from their unusual structures, which combine both a highly reactive metal-metal double bond and highly strained three-membered skeleton in one molecule. From all the cyclotrimetallenes described above, the reactivity has been studied for...
cyclotrisilenes, cyclotrigermenes and “mixed” compounds. The chemistry of the only reported cyclotristannene is still open for investigation.

1. Addition reactions

a. Reactions with CCl₄. The reactivity of cyclotrimetallenes with CCl₄ was studied in the case of cyclotrisilenes and ‘mixed’ cyclotrimetallenes. Thus, cyclotrisilene 4, 1-disilagermirene 22 and 2-disilagermirene 23 were reacted with an excess of CCl₄ to form the corresponding trans-dichloro derivatives 26–28 even at low temperature in nearly quantitative yield (Scheme 11)²³. As was mentioned before, the cyclotrisilene 1 also reacts with CCl₄ to produce the trans-1,2-dichloro derivative 2¹⁴. The reaction proceeds selectively to produce only one isomer — trans, which can be explained by the steric requirements. The crystal structure of compound 27 is shown in Figure 8. It is interesting that the dichloro derivatives 26–28 can be quantitatively converted back to the corresponding starting cyclotrimetallenes 4, 22 and 23 by treatment with t-Bu₃SiNa (Scheme 11)²³.

![Scheme 11](image)

FIGURE 8. ORTEP drawing of 1,2-dichloro-1,2,3,3-tetrakis[di-tert-butyl(methyl)silyl]-1,2-disilagermirane 27
2. Cycloaddition reactions
   

   i. Reactions with phenylacetylene. The behavior of cyclotrimetallenes toward phenylacetylene was surprisingly different, showing the different nature of the three-membered ring compounds composed of the Si, the Ge, or both Si and Ge atoms. Thus, reaction of phenylacetylene with mesityl-substituted cyclotrigermene 19 proceeds as a [2 + 2] cycloaddition reaction with the formation of the resulting bicyclic three- and four-membered ring compound 29 as orange crystals in the form of two stereoisomers 29a and 29b (Scheme 12). The crystal structure analysis of 29a showed a highly folded bicyclic skeleton with a dihedral angle between the planes of the three- and four-membered rings of 97.4° (Figure 9).

   ![Scheme 12](image-url)

   The reaction of the ‘mixed’ cyclotrimetallenes 22 and 23 with phenylacetylene also proceeds through the initial [2 + 2] cycloaddition of the first molecule of phenylacetylene across the E=Si (E = Si, Ge) double bond with the formation of the three- and four-membered bicyclic compounds 30 and 31. But the reaction does not stop at this stage: valence isomerization of the bicyclic compound takes place to form the silole type structures 32 and 33 with one Si=C and one Ge=C double bond, which in turn
quickly isomerizes to give the thermodynamically more stable siloles 34 and 35 with one Si=Ge and one C=C double bond (Scheme 13). The silole-type compounds 34 and 35 react with a second molecule of phenylacetylene in a [2 + 2] cycloaddition manner to give the final four- and five-membered bicyclic compounds 36 and 37. In the case of 2-disilagermirene 23, it was possible to isolate the intermediate silole 35, representing the first metalladiene of the type E=E'-C=C (E,E' — heavier Group 14 elements). Two examples of the isolable metalladienes of Group 14 elements have been recently reported by Weidenbruch’s group: hexakis(2,4,6-tri-isopropylphenyl)tetrasila-1,3-butadiene 44 and hexakis(2,4,6-tri-isopropylphenyl)tetragerma-1,3-butadiene 45.

The structure of compound 35 was determined by means of all spectral data. Thus, the $^{29}$Si NMR spectrum showed five resonances, of which three belong to the silyl substituents: 19.4, 26.6 and 30.1 ppm, the down-field signal at 124.2 ppm was attributable to the doubly bonded silicon atom and the up-field signal at $-45.6$ ppm corresponds to the endocyclic sp$^3$ Si atom. X-ray analysis of 35 revealed an almost planar five-membered ring, although the Si=Ge double bond has a twisted (trans-bent) configuration with a torsional angle Si(6)−Ge(1)−Si(2)−Si(5) of 38.6(1)$^\circ$ (Figure 10). The Si=Ge double bond length, which was determined experimentally for the first time, is 2.250(1) Å, which is intermediate between the typical values for Si=Si and Ge=Ge double bond lengths. From the experimental data, i.e. X-ray crystallography, the UV-Vis spectrum and reactivity of the silole 35, it was found that there is almost no conjugation between the two double bonds in the cyclopentadiene ring of 35. This seems to be curious since all the known cyclopentadiene compounds were described as fully conjugated systems, for which

Diels–Alder cycloaddition reactions are typical. Apparently, such unusual behavior is caused by both the great energy difference and the difference in the size of the atoms of the Si=Ge and C=C double bonds, which prevent an effective overlapping of the molecular orbitals of the two π-bonds necessary for real conjugation. In contrast, for the symmetrical heavier Group 14 elements containing 1,3-diene systems with two equal double bonds, such as 2,3-digerma-1,3-butadiene H₂C=GeH−GeH=CH₂, theoretical calculations have predicted about half the degree of conjugation compared with that of the parent 1,3-butadiene. The cyclotrisilene also readily reacts with phenylacetylene to form finally a bicyclic compound similar to that of 36 and 37. In this case the isolation of the cyclopentadiene-type compound was impossible due to its very short life time.
ii. Reactions with aldehydes and ketones. Reaction with carbonyl compounds is also very sensitive to the steric requirements. Thus, highly sterically protected tetrakis(tri-tert-butylsilyl)cyclotrigermene 5 does not react with benzaldehyde\(^{39}\), whereas the reaction of 1-disilagermirene 22 with benzaldehyde proceeds almost immediately to give a set of products depending on the reaction conditions and the ratio of the reagents (Scheme 14)\(^{50}\).

Thus, at room temperature 1-disilagermirene 22 reacts with one molecule of benzaldehyde to give the bicyclic three- and four-membered ring compound 38, similar to the above case of phenylacetylene\(^{22}\). Compound 38 can be considered as a kinetically controlled product, which presumably is stabilized by an interaction of the electron-rich phenyl group and the empty \(\sigma^*\)-orbital of the exocyclic Ge–Si bond. Nevertheless, such an arrangement of the phenyl group is not favorable due to the steric repulsion with silyl substituents on the Ge atom; therefore, upon heating at mild conditions compound 38 was isomerized quantitatively to a thermodynamically more stable compound 39, whose structure was established by X-ray analysis (Figure 11). Compound 39 has a highly folded skeleton with a dihedral angle between the two planes of 107.8°.

The initially formed bicyclic compound 38 has a highly strained and very reactive bridgehead endocyclic Si–Si bond. It can easily react with a second molecule of benzaldehyde by the insertion pathway to form a new bicyclic compound 40 with a norbornane type skeleton (Scheme 14 and Figure 12). Although this last reaction closely resembles the previous case of phenylacetylene\(^{22}\), the mechanism is evidently different: in the case of phenylacetylene the final product 36 is a result of \([2 + 2]\) cycloaddition of the second molecule of phenylacetylene across the new Si=Ge double bond, whereas in the case of benzaldehyde the final norbornane 40 is a result of the insertion of the second molecule of benzaldehyde into the strained Si–Si single bond. Apparently, the reactions of disilagermirenes with phenylacetylene and benzaldehyde have the same initial steps to form bicyclic compounds, but then the reaction pathways become different due to the different nature of these intermediate bicyclic compounds.

\end{align*}
\]

Intramolecular C=O insertion into Si-Ge bond

SCHEME 15
The reaction of 1-disilagermirene 22 with ketones is similar to the benzaldehyde case. Thus, reaction with butane-2,3-dione gives a final bicyclic product 41, which also has a norbornane type skeleton (Scheme 15, Figure 13). Formation of this compound can be reasonably explained by the initial [2 + 2] cycloaddition of one carbonyl group across the Si=Si bond to form the three- and four-membered ring bicyclic compound 42, followed by the isomerization of disilaoxetane 42 to an enol ether derivative 43. The intramolecular insertion of the second carbonyl group into the endocyclic Si−Ge single bond in 43 completes this reaction sequence to produce the final norbornane 41. In this case, C=O insertion occurred into the Si−Ge bond rather than the Si−Si bond, which is reasonable due to the weakness of Si−Ge bond.

b. [4 + 2] Cycloaddition reactions.

i. Reactions with 1,3-dienes. Conjugated dienes, such as 2,3-dimethyl-1,3-butadiene and isoprene, are traditionally widely used as trapping reagents, for both transient and stable dimetallenes of Group 14 elements to form the corresponding Diels−Alder adducts. While reacting with the cyclotrimetallenes of Group 14 elements, conjugated dienes have produced the corresponding [4 + 2] adducts in the form of fused three- and six-membered ring compounds. For example, the reaction of mesityl-substituted cyclotrigermene 19 with both 2,3-dimethyl-1,3-butadiene and isoprene yields bicyclic adducts 44 and 45 (Scheme 16).

X-ray analysis confirmed the structure of compound 44 (Figure 14). Only one of the two possible stereoisomers was formed, which corresponds to the attack of the isoprene on the Ge=Ge double bond from the mesityl side. This probably can be explained by the lower steric bulkiness of the mesityl group compared with the t-Bu₃Si group. Due to
SCHEME 16

FIGURE 14. ORTEP drawing of a [4 + 2] cycloadduct 44. Reproduced by permission of Wiley-VCH from Reference 21
steric reasons, the three $t$-Bu$_3$Si groups occupy the less hindered pseudoequatorial positions, whereas the mesityl group and CH$_2$C(Me)=CHCH$_2$ moiety occupy the pseudoaxial positions (Figure 14).

It is noteworthy that the bicyclic three- and six-membered compounds 44 and 45 can serve as precursors for both germylene and digermene at 70 °C$^{21}$. Such species can be effectively trapped by 2,3-dimethyl-1,3-butadiene to form germacyclopentene 48 and bicyclic compounds 49 and 50 (Scheme 17).

\[
\begin{align*}
(44) \quad & R = H \\
(45) \quad & R = Me
\end{align*}
\]

Mes = 2,4,6-Me$_3$C$_6$H$_2$

SCHEME 17

The most interesting point in these reactions is the ring contraction, which takes place in the intermediate digermacyclohexadienes 46 and 47 during reaction with diphenylacetylene (Scheme 18)$^{51}$. Thus, during thermolysis of the bicyclic
compounds 44 and 45, a formal migration of the CH₂ group from one Ge atom to another one in the intermediate digermenes 46 and 47 takes place, resulting in ring contraction to form germylgermylene species 51 and 52. These last germylenes can be trapped by diphenylacetylene to produce the corresponding germacyclopropenyl-substituted germacyclopentenes 53 and 54 (Scheme 18 and Figure 15). Similar digermene–germylgermylene rearrangement of tetramesityldigermene,⁵²,⁵³ and germasilene–silylgermylene rearrangement of tetramesitylgermasilene⁵³ were previously reported by Baines and Cooke.
3. Oxidation of cyclotrigermenes — formation of the ‘free’ germyl cation

It is well known that the cyclopropenium cation with a Hückel-type aromatic 2 $\pi$-electron system is the simplest and smallest aromatic compound, which is relatively stable due to its resonance stabilization despite the very large ring strain. Although the chemistry of the cyclopropenium cation is well established now, the analogues of this compound consisting of heavier Group 14 elements were unknown until recently. Theoretical calculations on the stability of $A_3H_3^+$ cations ($A = C, Si, Ge, Sn, Pb$) predicted a preference for the classical cyclopropenium cation structures with $D_{3h}$ symmetry for the carbon and silicon cases, whereas $C_{3v}$ hydrogen-bridged forms were expected to be favored for germanium, tin and lead. In contrast to these calculations, the first free germyl cation with a 2 $\pi$-electron system was reported by Sekiguchi and coworkers in 1997 as a classical cyclopropenium-type cation. Thus, tris(tri-1-tert-butylsilyl)cyclotrigermencium tetraphenylborate [(t-Bu$_3$SiGe)$_3$+$^+$TPB$^-$] (TPB$^-$ = tetraphenylborate) was prepared by the treatment of tetrakis(tri-1-tert-butylsilyl)cyclotrigermene with trityl tetraphenylborate in dry benzene and was isolated as air and moisture sensitive yellow crystals (Scheme 19).

![SCHEME 19](image)

The structure of 55 was determined on the basis of NMR spectral data and finally confirmed by X-ray crystallographic analysis (Figure 16). The three germanium atoms
form an equilateral triangle [Ge–Ge bond lengths 2.321(4)–2.333(4) Å and Ge–Ge–Ge bond angles 59.8(1)–60.3(1)]°. The Ge–Ge bond lengths observed in 55 are intermediate between the Ge=Ge double bond [2.239(4) Å] and the Ge–Ge single bond [2.522(4) Å] of the precursor 513. The closest distance between germanium and the aromatic carbon atoms of TPB− is greater than 4 Å, well beyond the range of any significant interaction. These structural features indicate that 55 has a cyclotrigermanium skeleton and it is a free germyl cation with a 2π-electron system. The aromatic stabilization of the cyclotrigermanium ion and the charge delocalization explain the observed lack of any close interaction with the counter anion.

However, the problem of TPB− was its chemical instability60, because 55 can survive in a solution of dichloromethane only at temperatures below −78 °C. [3,5-(CF3)2C6H3]4B− (TFPB−, tetrakis[3,5-bis(trifluoromethyl)phenyl]borate)61, (C6F5)4B− (TPFPB−, tetrakis(pentafluorophenyl)borate)62 and [4-(t-BuMe2Si)C6F4]4B− (TSFPB−, tetrakis[4-[tert-butyl(dimethyl)silyl]-2,3,5,6-tetrafluorophenyl]borate)63,64 are known to be stable borate anions, which can increase the stability of the resulting cyclotrigermanium ion. Therefore, the reactions of cyclotrigermenes 5 and 6 with Ph3C+•TFPB−, Ph3C+•TPFPB− and Ph3C+•TSFPB− were studied with the hope of obtaining the stable cyclotrigermanium salts65–67. In fact, the reaction of (t-Bu3Si)4Ge3 with Ph3C+•TFPB− in benzene at room temperature produced the salt (t-Bu3SiGe)3+•TFPB− 15, which was isolated as a yellow powder in 81% yield (Scheme 20). The reaction of 6 with Ph3C+•TFPB− in benzene also proceeded smoothly to give (t-Bu3GeGe)3+•TFPB− 56 in 76% yield. In a similar way, the reaction of 5 and 6 with Ph3C+•TPFPB− in benzene produced (t-Bu3SiGe)3+•TPFPB− 57 (80%) and (t-Bu3GeGe)3+•TPFPB− 58 (80%), respectively. The reaction of 5 with Ph3C+•TSFPB− produced (t-Bu3SiGe)3+•TSFPB− 59 as orange crystals in 88% yield. The resulting germyl cations can survive for extensive periods without decomposition both in solution and in the solid state (Scheme 20).

The molecular structure of 15 is shown in Figure 17. The three-membered ring consisting of germanium atoms is almost an equilateral triangle with the Ge–Ge

![FIGURE 16. ORTEP drawing of [(t-Bu3SiGe)3+•TPB−] 55. Reprinted with permission from Reference 58. Copyright 1997, American Association for the Advancement of Science](image-url)
differences of the three-membered ring almost equal, ranging from 2.3284(8) to 2.3398(8) Å [av. 2.3333(8) Å]. The Ge–Si bond lengths [Ge1–Si1, 2.425(1); Ge2–Si2, 2.442(1); Ge3–Si3, 2.444(1) Å] of 15 are shortened compared with those of 5 [2.629(7) Å for the Ge–Si bond length of sp³ Ge atom and 2.448(7) Å for the Ge–Si bond length of sp² Ge atoms]. The perspective view appears to show a weak electrostatic interaction
between the germanium and fluorine atoms. The three closest distances range from 3.823 to 5.097 Å; however, these distances are longer than the sum (3.57 Å) of the van der Waals radii for germanium and fluorine atoms.

X-ray diffraction data were also obtained for 59. Due to the steric bulkiness of the \(t\)-BuMe\(_2\)Si group attached to the \textit{para} positions of the phenyl rings of the borate anion, no interaction between the cation moiety and the counter anion can be found (Figure 18). As a consequence, the skeleton of the three-membered framework forms an equilateral triangle; the Ge−Ge bond lengths are 2.3310(8) for Ge1−Ge2, 2.3315(7) for Ge1−Ge3 and 2.3349(8) Å for Ge2−Ge3, and the Ge−Ge−Ge bond angles are 60.10(2)° for Ge2−Ge1−Ge3, 59.96(2)° for Ge1−Ge2−Ge3 and 59.94(2)° for Ge1−Ge3−Ge2. The structural features for 15 and 59 are practically the same as those of 55.

The evidence for the existence of the free cyclotrigermanium ion in solution was supported by the NMR spectroscopic data. The \(^1\)H, \(^13\)C and \(^{29}\)Si NMR chemical shifts for the cyclotrigermanium moiety of 15, 57 and 59 in CD\(_2\)Cl\(_2\) are practically the same. For example, the \(^{29}\)Si NMR chemical shifts of 15, 57 and 59 are independent of the counter anion. The \(^{29}\)Si NMR chemical shift of 15 is also essentially the same in different solvents, appearing at \(\delta = 64.0\) in CD\(_2\)Cl\(_2\), \(\delta = 64.2\) in CDCl\(_3\), \(\delta = 64.4\) in toluene-d\(_8\) and \(\delta = 64.5\) in Et\(_2\)O. This independence from both the counter anion and solvent clearly indicates that \((t\text{-}Bu_3SiGe)_3^+\) is a free germyl cation in solution. The large down-field shifted \(^{29}\)Si NMR resonance of \((t\text{-}Bu_3SiGe)_3^+\), relative to that of the precursor 5 (\(\delta = 37.2\) for the \(t\text{-}Bu_3Si\) substituent attached to the saturated Ge atom and 50.1 for the \(t\text{-}Bu_3Si\) group attached to the Ge=Ge double bond)\(^{13}\), is due to the positive charge of the cyclotrigermanium ion.

\[\text{FIGURE 18. ORTEP drawing of } [(t\text{-}Bu_3SiGe)_3^+\cdot\text{TSFPB}^-] 59.\text{ Reproduced by Permission of Wiley-VCH from Reference 67}\]
The positive charge is not localized on the germanium atoms, but is significantly transferred to the silicon centers. The atomic (Mulliken) charges on \((H_3SiGe)_3^+\) according to HF/6-31G* level calculations indicate a delocalization of the positive charge: \(-0.07\) for the ring germanium atoms and \(+0.64\) for the silicon atoms of the SiH3 substituents.

**III. EPILOGUE AND OUTLOOK**

The present review has no pretensions to be a comprehensive one and to cover all the chemistry of small ring systems containing heavier Group 14 elements: this field is quite vast and greatly exceeds the framework of this article. Here we have concentrated on the relatively narrow and rather new field of the unsaturated three-membered rings consisting of heavier Group 14 elements. In organic chemistry, cyclopropene, which is the smallest unsaturated ring system, and its derivatives are among the most important classes of organic compounds due to their enhanced reactivity caused by a great ring strain and existence of the endocyclic C=C double bond. Apparently, the heavy cyclopropene analogues, that is cyclotrимetallenes composed of Si, Ge, Sn and Pb atoms, would occupy a similar important position in the chemistry of Group 14 elements, since their high reactivity is even more pronounced than that of cyclopropene because of the extremely reactive endocyclic metal–metal double bond and the weakness of endocyclic metal–metal single bonds. Even now, cyclotrtrimetallenes, which quite recently were considered to be synthetically inaccessible, can be considered as unusual molecules, and their number is still very limited. The chemistry of such compounds, which often exhibit great differences in the structures, properties and reactivity from their carbon analogues, has started quite recently, and there are still many questions and problems to be solved. Thus, the Pb-containing representative—i.e. cyclotriplumbene—has not yet been prepared. Several possible combinations for the ‘mixed’ cyclotrtrimetallenes can also be imagined as the next target molecules. The reactivity of cyclotrtrimetallenes also needs to be studied in detail; moreover, the first preliminary investigations showed the extremely high synthetic possibilities of such compounds, since very rich chemistry can be developed from them. Thus, one can expect much progress in this ‘hot’ field of Group 14 elements chemistry in the near future, which will have an important impact on our understanding of the nature of bonding and reactivity in systems with elements heavier than carbon.

**IV. ACKNOWLEDGMENT**

We highly appreciate Dr. Masaaki Ichinohe and Mrs. Norihisa Fukaya, Tadahiro Matsuno, Hiroshi Sekiyama and Yutaka Ishida for their invaluable experimental contributions. We wish to thank Professor Shigeru Nagase for the theoretical calculations. This work was supported by a Grant-in-Aid for Scientific Research (Nos. 13029015, 13440185, 12042213) from the Ministry of Education, Science and Culture of Japan, and TARA (Tsukuba Advanced Research Alliance) fund.

I. INTRODUCTION

The polycyclic cage compounds of Group 14 elements heavier than carbon (i.e. tetrahedranes, cubanes, prismanes, etc.) have fascinated chemists for a long time because of their unique structures and expected unusual physico-chemical properties and reactivity\(^1\). It was quite reasonable to assume that such exotic compounds could possess properties...
different from their carbon analogues, arising from the highly rigid framework consisting of σ bonds with low ionization potentials. Despite the obviously great synthetic challenge, such strained polyhedranes of Si, Ge and Sn have not been prepared until recently, and were even considered to be synthetically inaccessible. The first breakthrough in their synthesis occurred in the late 80s, when reports on the synthesis of the first octasilacubane\(^2\) and hexagermaprismane\(^3\) were published in the scientific literature. Then, during the last decade, there was dramatic progress in the chemistry of such cage compounds, and many new derivatives have been prepared. To date, two tetrahedranes (one tetrasilatetrahedrane and one tetragermatetrahedrane), four prismanes (one hexasilaprismane, two hexagermaprismanes and one hexastannaprismane) and nine cubanes (five octasilacubanes, three octagermacubanes and one octastannacubane) have been described in the literature. Theoretical calculations\(^4\)–\(^6\) have found that the strain of the cage compounds is significantly decreased by the introduction of electropositive silyl groups. Therefore, in many cases, the successful preparation of the cage molecules has been achieved by using bulky silyl substituents both for the kinetic protection of the strained skeleton and to decrease the ring strain. In the present review we will be concerned mainly with the synthesis of the cage compounds, and the structural and chemical peculiarities arising from their unusual highly strained framework.

II. CAGE COMPOUNDS OF HEAVIER GROUP 14 ELEMENTS: TETRAHEDRANES, PRISMANES, CUBANES

A. Comparative Ring Strain of the Polyhedral Compounds: Theoretical Study

In organic chemistry it is well known that polyhedranes (C\(_{2n}\)H\(_{2n}\)), such as tetrahedranes (\(n = 2\)), prismanes (\(n = 3\)) and cubanes (\(n = 4\)), are highly strained, as their carbon bond angles greatly deviate from the normal tetrahedral value of 109.5°. Since no experimental values are available for the heavier analogues, their strain energies were calculated on the basis of the appropriate homodesmotic reactions\(^7\),\(^8\). Table 1 shows a comparison of the calculated strain energies for the carbon-, silicon-, germanium- and tin-containing polyhedral compounds. The strain energy of tetrasilatetrahedrane is similar to that of tetrahedrane. However, the ring strain of the silicon compounds decreases significantly with increasing number of four-membered rings, while in the case of carbon compounds the tendency is the opposite. It is noteworthy that hexasilaprismane and octasilacubane are less strained than prismane and cubane by 32 and 65 kcal mol\(^{-1}\), respectively. On going from carbon and silicon to germanium and tin atoms, the tendency is the same: in the tetrahedrane molecules there is only a small effect on the relief of strain\(^8\). Apparently, such a phenomenon originates from the high ring strain of the cyclotrimetallanes of Si, Ge and Sn atoms.

HF/6-31G* level for M = C and Si. HF/DZ(d) level for M = Ge and Sn.
\(^b\)The HF/DZ(d) values are 140.3 (Si\(_4\)H\(_4\)), 118.2 (Si\(_6\)H\(_6\)) and 99.1 (Si\(_8\)H\(_8\)) kcal mol\(^{-1}\). Reproduced by permission of John Wiley & Sons Ltd, from Reference 1d.
which is much larger than that of cyclopropane: cyclotrilsilane (38.9 kcal mol\(^{-1}\))\(^7\), cyclotrigermane (39.4 kcal mol\(^{-1}\))\(^8\), cyclotristannane (36.6 kcal mol\(^{-1}\))\(^8\) vs cyclopropane (28.7 kcal mol\(^{-1}\))\(^7\). However, the strain energies of prismane and cubane molecules containing four-membered rings are further decreased from silicon to germanium and tin compounds. This can be explained by the decrease of the ring strain in the four-membered rings: cyclobutane (26.7 kcal mol\(^{-1}\))\(^7\) > cyclotetrasilane (16.7 kcal mol\(^{-1}\))\(^7\) > cyclotetragermane (15.2 kcal mol\(^{-1}\))\(^8\) > cyclotetrestannane (12.2 kcal mol\(^{-1}\))\(^8\). Thus, there is a general trend of decreasing strain energies of the polyhedral compounds with increasing number of four-membered rings and on going from carbon to tin.

Such a trend is also shown by the larger members of the \([n]\)prismane family (\(M_{2n}H_{2n}\), \(n > 4\)). Figure 1 shows\(^5,9,10\) that the strain energies of persila\([n]\)prismanes (\(Si_{2n}H_{2n}\)) are 53.2 (\(n = 5\)), 70.1 (\(n = 6\)) and 141.0 (\(n = 8\)) kcal mol\(^{-1}\) smaller than those of the corresponding \(C_{2n}H_{2n}\) and even more on going from Si to Ge and Sn. The strain energy decreases when \(n\) increases from 2 to 5, because the number of four-membered rings increases and the bond angles in the \(n\)-membered rings approach the ideal tetrahedral angle of 109.5°. However, the strain sharply increases with \(n > 5\), despite the increasing number of four-membered rings, because of the increasing deviation of the bond angles (120° for \(n = 6\) and 135° for \(n = 8\)) in the \(n\)-membered rings from the tetrahedral angle. Thus, the minimum strain energy was calculated for \(n = 5\). Therefore, it is reasonable to expect a successful synthesis of \([5]\)prismanes, of which the perstanna[5]prismane has already been prepared\(^11\).

The origin of such differences in the ring strain of carbon and its heavy analogues can be reasonably explained by the difference in the hybridization character, since it is known that the heavier atoms have a lower tendency to form sp hybrid orbitals with high p-character, and they tend to maintain the ns\(^2\)np\(^2\) electronic configuration\(^8,9,12\). That

![FIGURE 1. The strain energies of the tetrahedrane and \([n]\)prismane systems (\(M_{2n}H_{2n}\)) calculated at the HF/6-31G\(^*\) level for \(M = C\) and Si and the HF/DZ(d) level for \(M = Ge\) and Sn. Reprinted with permission from Reference 5. Copyright (1995) American Chemical Society](image-url)
makes it favorable for the heavier atoms to form bond angles of ca 90° (that is, to form four-membered rings) and unfavorable to form bond angles of ca 60° (that is, formation of three-membered rings).

Such properties are also reflected in the relative stability of the M₆H₆ valence isomers (Table 2). It is well known that benzene (C₆H₆) is very stable due to cyclic delocalization of its six \( \pi \) electrons (aromatic stabilization), and it is much more stable than other strained valence isomers — Dewar benzene, benzvalene and prismane. However, the tendency is completely reversed in the case of heavier atoms: the isomers with a smaller number of double bonds are more favorable. As a result, the prismane structure becomes much more stable than the benzene structure on going from carbon to tin atoms.

### B. Tetrahedrane

#### 1. Tetrasilatetrahedrane

The only known example of the tetrasilatetrahedrane molecule, tetrakis(tri-tert-butylsilyl)tetrasilatetrahedrane 1, was reported by Wiberg in 1993 by the reaction of \(t\)-Bu\(_3\)Si–SiBr₂–SiBr₂–Si(Bu-t)\(_3\) with \(t\)-Bu\(_3\)SiNa in THF at \(−20^\circ\)C.\(^{16}\) The details of its synthesis as well as its physico-chemical characteristics are summarized in a recent review\(^{1d}\) and will not be considered in the present article.
2. Tetragermatetrahedrane

The synthesis of the title compound was reported several years later by the same authors, who had previously prepared tetrasilatetrahedrane in a similar way\(^\text{17}\). Thus, \(t\)-Bu\(_3\)Si—GeCl\(_2—\)GeCl\(_2—\)Si(Bu-t)\(_3\), which was prepared by the reaction of GeCl\(_4\) and \(t\)-Bu\(_3\)SiNa in THF at room temperature, was reacted with \(t\)-Bu\(_3\)SiNa in THF at \(-78^\circ\text{C}\). The tetragermatetrahedrane \(2\) was formed in a low yield together with some other products (Scheme 1).

\[
\begin{align*}
\text{GeCl}_2 \cdot \text{dioxane} & \quad \xrightarrow{\text{t-} \text{Bu}_3 \text{SiNa}} \quad \text{THF/RT} \\
\text{Ge} & \quad \text{Si(Bu-t)3} \\
\text{t-Bu}_3 \text{Si} & \quad \text{THF/} \text{78}^\circ\text{C}
\end{align*}
\]

**SCHEME 1**

Tetragermatetrahedrane \(2\) was also prepared by the reaction of dichlorogermylene–dioxane complex GeCl\(_2\)•C\(_4\)H\(_8\)O\(_2\) with \(t\)-Bu\(_3\)SiNa in THF at room temperature (Scheme 1). It is quite interesting that the same reaction, which leads to the tetrakis(tert-butylsilyl)cyclotrigermene at low temperature\(^\text{18}\), in this case results in the formation of a completely different compound (i.e. tetragermatetrahedrane) when performed at room temperature. The tetragermatetrahedrane \(2\) was isolated as intense red crystals, slowly hydrolyzable by water and rapidly oxidizable by air. Compound \(2\) can be reduced with sodium to form a mixture of products, from which \(t\)-Bu\(_3\)SiNa was identified by the trapping reaction with Me\(_3\)SnCl to form \(t\)-Bu\(_3\)Si—SnMe\(_3\).

The crystal structure of \(2\) (which cocrystallizes with the disilane \(t\)-Bu\(_3\)Si—Si(Bu-t)\(_3\)) was determined by X-ray diffraction, which showed the monoclinic unit cell of the crystals with the composition \(2(t\)-Bu\(_3\)Si\(_4\)Ge\(_4\)•(t-Bu\(_3\)Si\(_3\)) containing four molecules of \(2\) and two molecules of \(t\)-Bu\(_3\)Si—Si(Bu-t)\(_3\) (Figure 2). The Ge—Ge (av 2.44 Å) and Si—Ge (2.38 Å) distances are slightly longer than those in the parent H\(_3\)Ge—GeH\(_3\) (2.41 Å) and H\(_3\)Si—GeH\(_3\) (2.36 Å)\(^\text{19}\), respectively.

C. Prismanes

1. Hexasilaprismane

The first and sole example of hexasilaprismane, hexakis(2,6-diisopropylphenyl)hexasilaprismane \(3\), was prepared by Sekiguchi and coworkers in 1993 by the coupling reaction of \((2,6-(i-\text{Pr})_2\text{C}_6\text{H}_3)_2\text{SiCl}_2—\text{SiCl}_2—(2,6-(\text{Pr}-i)_2\text{C}_6\text{H}_3)_2\) with Mg/MgBr\(_2\) in THF at room temperature\(^\text{20}\). The synthesis and properties of hexasilaprismane, and its interesting photochemical isomerization to a hexasila-Dewar benzene, are described in a previous review article\(^\text{14}\).
2. Hexagermaprismanes

The first hexagermaprismane, hexakis[bis(trimethylsilyl)methyl]tetracyclo[2.2.0.0^2,6.0^3,5]hexagermane 4, was reported by Sekiguchi and coworkers in 1989\(^3\), even earlier than the corresponding silicon analogue. Bis(trimethylsilyl)methyl groups were chosen as the appropriate protecting groups, and Li (or Mg) metals as the coupling reagent. Thus, reaction of bis(trimethylsilyl)methyltrichlorogermane with Li in THF at \(-78^\circ\text{C}\) (or Mg in THF at 0°\text{C}) produced the hexagermaprismane 4, which was isolated by column chromatography as yellow-orange crystals in 12% yield in the case of Li (or 24% yield in the case of Mg) (Scheme 2)\(^{1c,5}\).

In the solid state, hexagermaprismane 4 was unexpectedly stable to air and moisture and decomposes only above 200°\text{C}. NMR spectral data fully correspond to a highly symmetrical structure of 4, showing only two singlets in the \(^1\text{H}\) (0.62 and 1.37 ppm) and
13C (4.08 and 29.8 ppm) NMR spectra, and only one signal at $-1.95$ ppm in the $^{29}$Si NMR spectrum. An electronic spectrum revealed an absorption maximum at 280 nm, tailing into the visible region ($ca$ 500 nm). The prismane 4 exhibits thermochromism: it is pale-yellow at $-196^\circ$C and intense orange at $200^\circ$C. Figure 3 shows the UV-Vis spectra of hexagermaprismanes 4 and 5.
FIGURE 3. UV-Vis spectra of hexagermaprismanes 4 and 5 in hexane

The X-ray crystallographic analysis of 4 showed the prismane structure consisting of six germanium atoms with $D_{3h}$ symmetry (Figure 4). The prismane skeleton is constructed from two triangular units [(Ge–Ge bond lengths of 2.578(6)–2.584(6) Å (av. 2.58 Å and Ge–Ge–Ge bond angles of 60.0(2)–60.1(1)° (av. 60°)) and the three rectangles [Ge–Ge bond lengths of 2.516(6)–2.526(6) Å (av. 2.52 Å and Ge–Ge–Ge bond angles of 88.5(2)–91.4(2)° (av. 90°))]. All the Ge–Ge bond lengths are considerably longer than the usual Ge–Ge bond lengths in other polygermanes (2.374–2.465 Å). Surprisingly, the Ge–Ge bond lengths in the triangles are longer than those in the rectangles, although calculations for the C and Si prismanes $^7,^{15,21}$ have predicted the opposite trends, as was found in the structures of the carbon analogues $^{22}$.

The second representative of the hexagermaprismanes, hexakis(2,6-diisopropylphenyl)tetracyclo[2.2.0.0$^{2,6}.0^{3,5}$]hexagermane 5, was synthesized several years later by the same authors by the reductive coupling of the corresponding precursor — (2,6-diisopropylphenyl)trichlorogermane with Mg in THF (Scheme 3) $^{20}$. Similar to the case of hexasilaprismane 3, the $^1$H and $^{13}$C NMR spectra of 5 show two non-equivalent isopropyl groups and aryl protons. From the low-temperature $^1$H NMR spectra, a $\Delta G^\ddagger$ value of 13.1 kcal mol$^{-1}$ for the rotational barrier of the aryl groups was found, which is much smaller than that of hexasilaprismane 3, due to the increased Ge–C$_\text{ar}$ bond length (1.983–1.993 Å, av. 1.988 Å). The hexagermaprismane 5 is less stable than the hexasilaprismane 3 toward atmospheric oxygen.

The choice of the reducing agent is quite important. Thus, reduction of the precursor (2,6-diisopropylphenyl)trichlorogermane with Mg/MgBr$_2$ in THF resulted in the formation of tetrakis(2,6-diisopropylphenyl)digermene $^{21}$ instead of prismane 5.
The crystal structure of 5 is similar to that of prismane 4 (Figure 5). Its structural parameters are listed in Table 3. The prismane skeleton is made from two triangular units [Ge–Ge bond lengths of 2.497–2.507 Å (av. 2.503 Å and Ge–Ge–Ge bond angles of 59.8–60.1° (av. 60.0°)] and the three rectangles [(Ge–Ge bond lengths of 2.465–2.475 Å (av. 2.468 Å) and Ge–Ge–Ge bond angles of 89.0–91.1° (av. 90°)].

As in the case of prismane 4, the cyclopropyl Ge–Ge bond lengths are longer than those in the rectangular units. All the Ge–Ge bond lengths in 5 are elongated compared with the normal ones (2.40 Å), although they are shorter than those in cyclotrigermane (R₂Ge)₃ (R = 2,6-dimethylphenyl: av. 2.541 Å)²⁴. The Ge–Ge bond lengths in 5 are somewhat shorter than those calculated for the parent Ge₆H₆ (2.502 Å for the triangular units and 2.507 Å for the rectangular units)⁸.

Irradiation of the hexagermaprismane 5 with light of 360–380 nm produced new absorption bands at 342, 446 and 560 nm due to the hexagerma-Dewar benzene 6 at low temperature, which seems to be quite similar to the case of hexasilaprismane to hexasil-Dewar benzene isomerization (Scheme 4)¹⁵. Excitation of the new bands with light of wavelength longer than 460 nm led to the regeneration of the starting hexagermaprismane 5. The hexagerma-Dewar benzene 6 also gradually reverted to the starting prismane 5 at temperatures above −160 °C.
3. Hexastannaprismane

The final representative of the prismanes consisting of the heavier Group 14 elements, hexastannaprismane, was synthesized quite recently by Wiberg’s group. The reaction of \( \text{Sn}\left[\text{N(SiMe}_3\right]_2 \) with \( t-\text{Bu}_3\text{SiNa} \) in pentane/tert-butyl methyl ether at \(-78^\circ C \) produced

a dark-blue reaction mixture from which dark-violet crystals were precipitated in two days (Scheme 5). These crystals are stable at room temperature in the absence of air and water, and decompose in the presence of organic solvents above 5 °C. Although it was impossible to obtain unambiguous NMR data due to the very low solubility of the compound in THF or toluene, the structure was determined by X-ray diffraction. It was found that the crystals contain hexakis[tri(tert-butyl)silyl]triprismohexastannane 7 (Figure 6) together with hexakis[tri(tert-butyl)silyl]disilane and tert-butyl methyl ether.

The hexastannaprismane 7 comprises a near-equilateral Sn6 prismane framework with almost parallel Sn3 faces that are only slightly twisted away from each other. The three Sn–Sn distances between the Sn3 faces of the Sn6 prismane are 2.91 Å, whereas, within the Sn3 faces, two of the Sn–Sn bonds are also 2.91 Å and the other one is 2.94 Å. They are slightly longer than the sum of the radii of two Sn atoms (2.80 Å)\(^2\), probably due to steric reasons. The average Si–Sn distances are 2.71 Å, which is longer than the sum of the radii (2.57 Å)\(^2\), but similar to the Si–Sn distances in \((t\text{-Bu}_3\text{Si})_2\text{SnCl}_2\) (2.70 Å)\(^2\).

The mechanism of formation of the hexastannaprismane 7 is not evident, although the authors have suggested the initial substitution of the amide groups by \(t\text{-Bu}_3\text{Si}\) groups with formation of the stannylene \((t\text{-Bu}_3\text{Si})_2\text{Sn}^*\), the dimerization of which to form the distannene \((t\text{-Bu}_3\text{Si})_2\text{Sn}=\text{Sn}(\text{Bu}-t)_3\)_2 does not take place due to steric reasons. Apparently, the oligomerization of the stannylene \((t\text{-Bu}_3\text{Si})_2\text{Sn}^*\) proceeds by elimination of the \(t\text{-Bu}_3\text{Si}\) radicals, which subsequently dimerize to form the disilane \(t\text{-Bu}_3\text{Si}=\text{Si}(\text{Bu}-t)_3\).

4. Comparison of the prismane structures

Table 4 summarizes the structural parameters of prismane molecules (\(M_6\text{H}_6; M = C, Si, Ge, Sn\)) together with the calculated values for \(R=H\). The \(M–M\) bonds within and between the three-membered rings are denoted as \(a\) and \(b\), respectively. The calculations predicted that \(a\) is shorter than \(b\) for \(R = H\)\(^7,8\), which is in accordance with the experimental data

for prismane$^{28}$ and its derivatives C$_6$R$_6$ (R = Me$^{29}$, SiMe$_3$$^{30}$). The theory shows that the bond length difference between $a$ and $b$ decreases significantly as M becomes heavier. It is interesting that, in contrast to the theoretical calculations, $a$ is longer than $b$ in Si$_6$R$_6$ [R = 2,6-(i-Pr)$_2$C$_6$H$_3$]$^{20}$], Ge$_6$R$_6$ [R = 2,6-(i-Pr)$_2$C$_6$H$_3$]$^{20}$, R = CH(SiMe$_3$)$_2$$^3$] and Sn$_6$R$_6$ (R = $t$-Bu$_3$Si$^{25}$).

D. Cubanes

1. Octasilacubanes

Octasilacubanes seem to be the most widely studied cage compounds, several examples of their reactivity having been described. To date, five examples of the octasilacubanes have been reported in the literature\(^{1d,2,31–36}\). Their synthesis, as well as structural parameters and reactivity, were summarized in a recent review\(^{1d}\).

2. Octagermacubanes

To date, three examples of octagermacubanes have been described in the literature. For all of them, the crystal structures were determined by X-ray crystallography. The
Scheme 6

\[
\text{Mg/MgBr}_2 \xrightarrow{\text{THF}} \text{GeGePh} \xrightarrow{\text{cis-cis-trans}} \text{HCl/AlCl}_3 \xrightarrow{\text{benzene}} \text{trans-trans-GeGeCl} \xrightarrow{\text{THF}} \text{Mg/MgBr}_2
\]
first two octagermacubanes were reported by Sekiguchi and coworkers in 1992. For the preparation of alkyl substituted octagermacubane, 1,2,3,4-tetrachloro-1,2,3,4-tetrakis(1-ethyl-1-methylpropyl)cyclotetragermane \( \text{8} \) was selected as a precursor (Scheme 6). To design this compound, condensation of dichloro(1-ethyl-1-methylpropyl)phenylgermane with Mg/MgBr\(_2\) in THF was performed to give a mixture of isomeric cyclotetragermanes in 72\% yield. These last compounds were reacted with gaseous HCl in the presence of AlCl\(_3\) in benzene with the formation of \( \text{8} \) in a \textit{trans-trans-trans} configuration in 45\% yield. The octakis(1-ethyl-1-methylpropyl)pentacyclo[4.2.0.0\(_2\),5.0\(_3\),8.0\(_4\),7]octagermane \( \text{9} \) was obtained by the coupling reaction of \( \text{8} \) with Mg/MgBr\(_2\) in THF in 16\% yield as yellow crystals with a melting point above 215 °C (Scheme 6). Figure 7 shows the UV-Vis spectra of octagermacubane \( \text{9} \) and \( \text{10} \).

The \(^1\text{H}\) and \(^{13}\text{C}\) NMR spectra correspond well to the structure, showing only signals belonging to alkyl substituents. The UV-Vis spectrum of \( \text{9} \) showed an absorption maximum at 240 nm (\( \varepsilon = 48700 \)) tailing to the visible region (Figure 7). In the solid state the cubane \( \text{9} \) was relatively stable to moisture and air. The same compound \( \text{9} \) can also be obtained by a direct coupling of (1-ethyl-1-methylpropyl)trichlorogermaine with Mg/MgBr\(_2\) in THF in 3\% yield. Despite the low yield, such a method has the advantage of a simple one-pot synthesis.

The aryl-substituted octagermacubane, octakis(2,6-diethylphenyl)pentacyclo[4.2.0.0\(_2\),5.0\(_3\),8.0\(_4\),7]octagermane \( \text{10} \), was synthesized by the dehalogenative coupling of (2,6-diethylphenyl)trichlorogermaine with Mg/MgBr\(_2\) in THF in 1\% yield as yellow crystals (Scheme 7). This compound was found to be less stable to atmospheric moisture and
air, which is evidence for the lower steric bulkiness of 2,6-diethylphenyl substituents compared with that of the 1-ethyl-1-methylpropyl groups.

For the mechanism of the formation of cubane molecule 9, the cyclotetr germene 11 was proposed as the reactive intermediate\textsuperscript{1c}, which can dimerize in a [2 + 2] cycloaddition manner to form \textit{syn} and \textit{anti} dimers 12 and 13 (Scheme 8). The former (12) would produce the octagermacubane 9, whereas the latter (13) produces ladder-type polygermanes 14.

*aSee Figure 8 for designations.

The crystal structure of 10 was established by X-ray diffraction to show an almost perfect cubic framework (Figure 8). Its structural parameters are listed in Table 5. The Ge–Ge bond lengths are 2.478–2.503 Å (av. 2.490 Å), which is close to, but slightly shorter than, that of the 2.527 Å calculated for Ge₈H₈. The Ge–Ge–Ge bond angles are 88.9–91.1° (av. 90.0°). The exocyclic Ge–C_car bonds (1.982 Å) are slightly elongated compared with the normal Ge–C_ar bond lengths (1.95 Å). Due to steric reasons, the Ge–Ge–C_ar bond angles (av. 124.6°) are expanded. The cubic crystal structure was also found for the octagermacubane 9 with Ge–Ge bond lengths of 2.534 Å (av.) and Ge–Ge–Ge bond angles of 90.0° (av.).
The last representative of octagermacubanes, octakis(1,1,2-trimethylpropyl)pentacyclo[4.2.0.0²,5.0³,8.0⁴,7]octagermane 15, was reported quite recently by Matsumoto’s group.38 The synthetic strategy for its preparation was essentially the same, as described above. Thus, (1,1,2-trimethylpropyl)trichlorogermane was reacted with Mg/MgBr₂ in THF at room temperature to form octagermacubane 15 in 3% yield as yellow crystals (Scheme 9). The structure of 15 was established on the basis of spectral data. Thus, the ¹H and ¹³C NMR spectra were fully consistent with the high symmetry of the molecule, revealing three resonances in the ¹H NMR and four in the ¹³C NMR spectra, indicating the equivalence of all substituents.

\[
\begin{align*}
\text{(Me₂CHCMe₂)GeCl₃} & \xrightarrow{\text{Mg/MgBr₂}} \text{THF/RT} \\
\text{(15)} & \quad R = \text{CMe₂CHMe₂}
\end{align*}
\]

**SCHEME 9**

The crystal structure of 15 was determined by X-ray analysis, which displayed the cubic skeleton of 15 with Ge—Ge bond lengths of 2.494–2.540 Å (av. 2.516 Å), which are slightly longer than those of the above-mentioned octagermacubane 10 (av. 2.490 Å)²¹ (Figure 9). The Ge—Ge—Ge bond angles lie between 88.0 and 91.9° (av. 90.0°). The exocyclic Ge—C bonds are slightly elongated (2.037–2.056 Å, av. 2.046 Å) in comparison with the octagermacubane 10 (av. 1.982 Å)²¹.

The highly strained Ge₈ framework of 15 causes interesting electronic properties. Thus, the oxidation potential of 15 (0.22 V) is much lower than that of the corresponding octasilacubane with the same substituents (0.43 V). This suggests that the HOMO of 15 lies at a higher level than that of the octasilacubane. However, in the UV-Vis spectrum of 15 there is a hypsochromic shift in comparison with octasilacubane (236 nm vs 252 nm). Such a hypsochromic shift is likely due to the greater energy separation between the HOMO and LUMO, presumably because of the high-lying LUMO in 15. Such a suggestion was supported by the electron transmission spectroscopy study of oligogermaines, which found that the LUMO (σ*) of Me₃GeGeMe₃ shifts by 0.30 eV to higher energy in comparison with σ* of Me₃SiSiMe₃.

Due to the low oxidation potential, cubane 15 is reactive toward electrophiles. Thus, chlorination of 15 with PCl₅ in benzene at room temperature finally gave the mixture of endo,exo- and exo,exo-4,8-dichlorooctakis(1,1,2-trimethylpropyl)tetracyclo[3.3.0.0²,7.0³,6]octagermanes 16 in 7 and 37% yield, respectively (Scheme 10).³⁸ The absence of the endo,endo-isomer could be explained by the exclusive generation of the intermediate 17. The lower steric hindrance of the exo-isomer is most likely responsible for the higher yield of exo,exo-16. The frameworks of type 16 have been reported previously by Sekiguchi and coworkers (t-Bu₈Ge₈Cl₂)⁴⁰ and Weidenbruch and coworkers (t-Bu₈Ge₈Br₂)⁴¹, who...
prepared these compounds by the reductive coupling of the tert-butyl substituted halogermanes with lithium naphthalenide. Treatment of compound 16 with sodium in toluene at 120 °C regenerated the starting octagermacubane 15 in 50% yield.

3. Octastannacubane

There is only one precedent for the preparation of octastannacubane reported by Sita and Kinoshita in 1990\textsuperscript{42}. The thermolysis of hexakis(2,6-diethylphenyl)cyclotristannane at 200–220 °C produced the deep red octastannacubane 18 together with the blue-violet pentastanna[1.1.1]propellane 19\textsuperscript{43}. Both compounds have been isolated by chromatography on silica gel (Scheme 11). Finally, the octastannacubane 18 was purified by recrystallization from pentane in 0.76% yield. The spectral data of 18 support the Sn\textsubscript{8}R\textsubscript{8} structure. Thus, the \(^1\)H NMR spectrum showed the equivalence of all substituents on the NMR time scale with four resonances for Et and aryl protons. In contrast to other known polycyclic polystannanes\textsuperscript{43,44} there is only a small rotational barrier about the Sn–C\textsubscript{aryl} bonds in 18, which implies lower steric congestion among the substituents. The \(^{119}\)Sn NMR spectrum revealed only one resonance at +44.3 ppm with two pairs of satellites \([\(1^J(\text{Sn}^{119}–\text{Sn}^{117}) = 1576 \text{ Hz} \text{ and } 2^J(\text{Sn}^{119}–\text{Sn}^{117}) = 1345 \text{ Hz}\)]\). The red crystals of 18 exhibit thermochromic properties: they become pale yellow at −196 °C. In the presence of air the toluene solutions of 18 decolorize in a few minutes. The UV-Vis spectrum of

SCHEME 11
18 in hexane exhibits no absorption maxima in the region 360–900 nm \( \lambda_{\text{max}} = 275 \text{ nm} \) (\( \varepsilon = 112000 \)), 320 nm (sh) (32000), 450 nm (sh) (2000)).

The X-ray analysis confirmed the cubic structure of 18 with Sn–Sn bond lengths of 2.839(2)–2.864(2) Å and all Sn–Sn–Sn bond angles nearly 90° (Figure 10). These structural parameters are in close agreement with those calculated for the parent Sn\(_8\)H\(_8\) octastannacubane (Sn–Sn bond length 2.887 Å and Sn–Sn–Sn bond angles 90°)\(^8\).

The mechanism of the formation of cubane 18 is not clear, although the authors have discussed the possible intermediate species RSn, which can be generated by the disproportionation \( 2R_2Sn \rightarrow RSn + R_3Sn^* \). A similar disproportionation of stannylene [(Me\(_3\)Si)\(_2\)CH]\(_2\)Sn has been observed under photolysis\(^{45}\). Such RSn species then undergo rapid oligomerization to form a family of \((RSn)_n\) compounds, of which the octastannacubane molecule is either the thermodynamically or kinetically favored member. A similar mechanism for the formation of cyclopolystannanes \((R_2Sn)_n\) by the oligomerization of transient stannylenes R\(_2\)Sn has been proposed previously\(^{46,47}\).

\[\text{FIGURE 10. ORTEP drawing of octastannacubane 18. Reprinted with permission from Reference 43. Copyright (1989) American Chemical Society}\]
It is interesting that the thermolysis of cyclotristannane in the presence of benzophenone increased the yield of octastannacubane 18 to 3.6%, probably due to complexation of the intermediate R₂Sn species by benzophenone. Except for the previously reported octastannacubane 18 and pentastanna[1.1.1]propellane 19, decakis(2,6-diethylphenyl)descastannana[5]prismane 20 was also formed (Scheme 11). The structure of the [5]prismane 20 was also established by X-ray diffraction, showing that the Sn–Sn bond lengths of 20 (av. 2.856 Å) are essentially the same as those of 18 (av. 2.854 Å).

4. Comparison of the cubane structures

Table 6 shows a comparison of the geometries [both experimental (X-ray) and calculated] of the cubane (C₈H₈)₄₈ and heavy cubane molecules M₈R₈ (M = Si, Ge, Sn; R = 2,6-Et₂C₆H₃). The M–M–M bond angles in M₈R₈ range from 89 to 91°, indicating the almost perfect cubic skeleton for these structures. The M–M bond lengths of 2.399 Å for Si, 2.490 Å for Ge and 2.854 Å for Sn are in good agreement with the calculated values of 2.382 Å for Si, 2.527 Å for Ge and 2.887 Å for Sn. The range of the M–M–C_ar bond angles increases in the order: 121–128° for Si, <120–130° for Ge, <117–133° for Sn. This implies a decrease in the steric congestion between the neighboring groups due to the elongation of the M–C_ar bond from silicon to tin: 1.911 Å for Si, <1.982 Å for Ge, <2.193 Å for Sn.

III. CONCLUSIONS AND OUTLOOK

The cage compounds of heavier Group 14 elements, which quite recently were considered as exotic molecules, now constitute an important class of organometallic compounds. Their specific structural and chemical characteristics, which are sometimes completely different from those of their carbon analogues, cause a permanent and increasing interest.

for researchers. Despite the great achievements of the last decade, there are still many synthetic challenges in the field of cage compounds. Thus, tetrastannatetrahedrane and all Pb-containing polyhedral compounds are still waiting to be prepared; undoubtedly, their unusual elegant design and potentially interesting properties will stimulate chemists to find methods for their synthesis. The reactivity of the cage compounds is also open for detailed investigation, since one can expect a very interesting chemistry in such highly strained molecules. The evident importance of such problems allows us to hope for significant progress in this field in the near future.

Quite recently after submission of this manuscript the remarkable paper describing the second example of octastannacubane compound was reported by Power and Eichler. This new octastannacubane $\text{Sn}_8(2,6-(2,4,6-\text{Me}_3\text{C}_6\text{H}_2)_2\text{C}_6\text{H}_3)_4$ was prepared by a coupling reaction of the aryltin halide $\text{Sn}(\mu-\text{Cl})(2,6-(2,4,6-\text{Me}_3\text{C}_6\text{H}_2)_2\text{C}_6\text{H}_3)_2$ with potassium in THF. X-ray analysis showed a highly distorted cubane structure, in which only four of the tin atoms carry substituents and the other four tin atoms are unsubstituted. the Sn–Sn distances fall in the range 2.853(2)–3.107(2) Å, which is usual for the $\text{Sn}_n\text{R}_n$ clusters.

IV. ACKNOWLEDGMENT

We thank Professors Hideki Sakurai and Shigeru Nagase for helpful discussions and useful advice. We are also grateful to C. Kabuto, T. Yatabe and H. Naito for their experimental contributions. This work was supported by a Grant-in-Aid for Scientific Research (Nos. 13029015, 13440185, 12042213) from the Ministry of Education, Science and Culture of Japan, and TARA (Tsukuba Advanced Research Alliance) Fund.

II. INTRODUCTION AND OUTLINE

A. Introduction

The extensive investigations of five- and six-coordinated heavy group 14 elements, especially tin, are due to the work of the last two decades. The large number of publications, annual reviews and surveys are devoted to separate aspects of the chemistry of these compounds and concern mostly extra-coordinate species (see, for example, reviews and monographs dedicated to organogermanium\(^1,2\), organotin\(^3–5\) and organolead\(^6,7\) compounds and references cited therein). The inter- and intramolecular D → M donor–acceptor bonds are common characteristics especially for tin(IV) compounds\(^4,5,8,9\). Up to now the number of hypervalent organic compounds of group 14 elements given in the Cambridge Structural Database is 104 (Ge), 1473 (Sn) and 52 (Pb)\(^10\).

The increasing interest in extra-coordinate derivatives of group 14 elements is caused by their structural peculiarities, their high reactivity and also by the possibility of using them for studying dynamic processes and modeling the pathway of nucleophilic substitution reactions at the central atoms. However, only a few publications deal with a model of hypervalency.

The purpose of the present chapter is to review the investigations dealing with the synthesis, structure and reactivity of hypervalent germanium, tin and lead compounds. The structures and properties of these compounds still remain a challenge. Many novel and unusual structures were elucidated by the X-ray diffraction technique.

In this chapter we discuss the chemistry of germanium, tin and lead species in which at least one organic group is bonded to carbon. Similar silicon compounds will sometimes be discussed for comparison. Synthetic details will be mentioned mostly for the compounds recently reported. Species without any M–carbon bond will also be described.

B. Outline

According to the formalism of Akiba\(^11\) hypervalent compounds are compounds of the main group elements (\(sp\) elements: Groups 1, 2, 13–18) those contain a number (\(N\)) of formally assignable electrons of more than the octet in a valence shell directly
associated with the central atom (X) which is directly bound with a number \((L)\) of ligands (substituents). The \(N\-M\-L\) designation is rather convenient for the classification of hypervalent structures. A trigonal bipyramid (TBP) or, more rarely, a square pyramid (SP) as well as an octahedral (Oh) arrangement of the metal atom are typical for germanium, tin and lead in pentacoordinate 10-M-5 and hexacoordinate 12-M-6 compounds, respectively.

The pronounced acceptor ability of the tetravalent germanium, tin and lead atoms, as well as the similar structures of compounds of other group 14–18 elements containing a penta- and hexacoordinate central atom, are usually interpreted (by analogy with transition metals) by assuming that the bonding process involves not only s and p AOs but also the vacant d AOs localized within the valence shell (the d orbital concept)\(^{12–14}\). The group 14 atoms (Ge, Sn and Pb) have five vacant nd AOs, the participation of which can in principle lead to penta- and hexacoordinate states. It was stated, however, that d AOs of these elements were so diffuse that they could not participate in the bonding\(^{15–18}\).

Another concept of hypervalent bonding suggests representation of the structures of penta- and hexacoordinate species without substantial contribution from nd orbitals. This concept is based on the idea of a three-center four-electron (3c-4e) bonding\(^ {19–21}\) for orbital-deficient compounds and was presented in a generalized form by Musher in 1969: ‘Hypervalent molecules are ions or molecules of the elements of Groups 15–18 bearing more electrons than the octet (nine or more) within a valence shell’\(^ {22}\). Hypervalent bonds in high-coordinate group 14 compounds differ from similar bonds of sulfur, phosphorus and chlorine derivatives, since the lone electron pair in this case is supplied by the ligand. According to Musher’s classification\(^ {22}\), considering 10-M-5 and 12-M-6, hypervalent compounds of germanium, tin and lead contain hypervalent bonding of the second kind (HV\(\text{II}\)), in which the central atom has no ns\(^2\) lone pair.

This model implies that the TBP M atom could use its nsp\(^2\) orbitals for bonding with the equatorial ligands to form two-center bonds, and its np\(_z\) orbital could be involved in the interaction with an appropriate orbital of the axial substituent X and a lone electron pair of the donor atom to form a hypervalent, 3c-4e bond in the axial moiety D \(\rightarrow\) M–X. The simplest MO diagram of a 3c-4e bond may be represented by three molecular orbitals: bonding (b), nonbonding (nb) and antibonding (ab) (Scheme 1).

The following conditions for the formation of hypervalent bonds have been stated\(^ {22,23}\):

1. These bonds can be formed when ligands are more electronegative than the central M atom.

2. The most electronegative substituents of those surrounding the M atom participate in a hypervalent bond and tend to occupy the axial positions in a trigonal-bipyramidal molecule.

3. The M–X bond lengths in penta- and hexacoordinate compounds are longer than those in similar tetrahedral molecules.

Hypervalent bonds in hexacoordinate compounds are formed in a similar fashion: the four equatorial M–X bonds (two 3c-4e bonding) in Oh are longer and more polar than the two axial bonds.
SCHEME 1. The simplest MO diagram of a 3c-4e bonding in hypervalent D → M–X fragment

In connection with the use of the hypervalent concept as an explanation of mutual cis/trans-influence in penta- and hexacoordinated compounds of group 14 elements, the experimental\textsuperscript{24–29} and theoretical\textsuperscript{30,31} works and references cited therein should be consulted.

In spite of some critical remarks\textsuperscript{32,33}, the hypervalent model is successfully used in interpreting the results of physicochemical investigations\textsuperscript{34–36}. For discussion on using the term ‘hypercoordinate’ instead of ‘hypervalent’, see Reference 37.

The development of the hypervalency concept was discussed in general\textsuperscript{11}. This model was concerned with the group 14 elements\textsuperscript{38}. The ability of the tin atom to expand the coordination sphere in organotin compounds was established in the early 1960s, when an oligomeric structure was suggested for trimethyltin fluoride\textsuperscript{39} and trimethyltin carboxylates\textsuperscript{40} on the basis of IR data. It should be pointed out that the trimethyltin chloride–pyridine adduct was the first pentacoordinate organotin compound structurally characterized by X-ray diffraction in 1963\textsuperscript{41}.

In contrast to silicon, for which the number of known compounds has grown rapidly over the last 15 years\textsuperscript{36,42}, little has been cited in the literature concerning the hypervalency of germanium\textsuperscript{1,8}, despite the fact that Ge exhibits a greater hypervalency than Si.

\textsuperscript{a}$r_{\text{cov}} = 1.223$ Å\textsuperscript{45} and $r_{\text{vdv}} = 2.15$ Å\textsuperscript{46}. The latter value was obtained from reliable van der Waals radius for Si (2.10 Å\textsuperscript{46}) and taking into account the difference between the covalent radii of Si (1.169 Å\textsuperscript{45}) and Ge. ($r_{\text{vdv}} = 2.11$ Å was obtained by Boyd\textsuperscript{47}.)

\textsuperscript{b}$r_{\text{cov}} = 1.42$ Å\textsuperscript{45} and $r_{\text{vdv}} = 2.17$ Å\textsuperscript{46}. ($r_{\text{vdv}} = 2.15$ Å was obtained by Boyd\textsuperscript{47}.)

\textsuperscript{c}$r_{\text{cov}} = 1.48$ Å\textsuperscript{45} and $r_{\text{vdv}} = 2.02$ Å\textsuperscript{46}.
Hypervalent compounds are common in the case of lead, rather than the tetrahedral ones\textsuperscript{7,8,43}. However, the coordination chemistry of hypervalent lead compounds has been much less studied than that of hypervalent organotin compounds, probably due to the well-known high toxicity of organolead derivatives. The progressive lowering of the three-center interaction for the group 14 column of the Periodic Table and the marked drop for lead can be accounted for in terms of the relativistic effect\textsuperscript{44}.

In the following sections we shall compare the bond lengths in hypervalent compounds to those of their 'standard' tetravalent derivatives as well as the sum of van der Waals radii of the corresponding atoms. These data are summarized in Table 1 and will not be mentioned further in the text discussing interatomic distances.

The various donor–acceptor complexes of carbene analogues $R_2M$: ($X_2M \rightarrow M'$ and $D \rightarrow MX_2$, $M = \text{Ge, Sn and Pb}$; $M' = \text{transition metal, D} = \text{Lewis base}$) and doubly bonded germanium, tin and lead derivatives ($D \rightarrow X_2M = Z, Z = MX_2, CR_2, O, NR$ etc.) are not considered in this review.

### III. SELF-ASSOCIATES

The intermolecular complexes of germanium(IV), tin(IV) and lead(IV) organohalides and tetrahalides with halide ions and neutral N-, O-, S- or P-donors, including electron donor solvents, have been well known for a long time. An analysis of the data on their stability was well documented in the literature\textsuperscript{8,26,48–56}. The presence of the electronegative substituents is essential for the formation of such complexes. Their stabilities decrease on increasing the number and the size of alkyl substituents at the central atom, as well as on increasing the size of the halogens. Lewis acidity increases in the sequence $\text{Si} < \text{Ge} \ll \text{Sn} < \text{Pb}$ and the largest change takes place on going from germanium to tin\textsuperscript{57,58}. Based on the enthalpies and equilibrium constants, compounds $R_2SnX_2$, $RGeX_3$ and $SiX_4$ ($R = \text{Alk, Ar}; X = \text{Hal}$) are closely related in their ability to form complexes with halide ions and neutral donors\textsuperscript{57–63}.

The stoichiometry of the complexes formed depends on the nature of organometallic halides. With monodentate ligands, triorganohalides form 1 : 1 complexes containing a pentacoordinated central atom. Diorganodihalides, organotrihalides and tetrahalides as a rule form 1 : 2 complexes with hexacoordinate central atom and less often pentacoordinate complexes.

The reviews mentioned above tabulate the data on the complexes discussed above, and this information is not repeated here. For completion, we discuss a few examples and compare some of the properties of inter- and intramolecular complexes.

Neutral compounds of heavy group 14 elements having donor atoms in monodentate ligands can be tetrahedral in the solution. However, in this case the environment for the element in the solid state can be five-coordinate due to hypervalent bridges. Self-association can be also observed for pentacoordinate species when the donor atom forms a unidentate bridge across the six-coordinate centers. The self-association is also characteristic of anionic species (Sections IV.A and IX.A). For a tin atom the intermolecular coordination is observed very frequently\textsuperscript{64}. As a rule it results in a polymeric structure mainly via the oxygen atom\textsuperscript{65}. However, dimers and other simple cyclic hypervalent structures are formed only seldom.

#### A. $N \rightarrow M$ Coordination

The relative ability of group 14 atoms to increase the coordination number up to five is clearly shown by comparing crystal structures of such compounds as $Me_3MCN$ ($M = \text{Si, Ge and Sn}$). The minimal intermolecular contact between $M$ and $N$ atoms for silicon
(3.66 Å) corresponds to the sum of van der Waals radii and the silicon atom coordination is close to tetrahedral. For germanium, the N → Ge distance (3.57 Å) is closer than the sum of van der Waals radii and the silicon atom coordination is close to tetrahedral. In Me₃SnCN, the tin atom is in a TBP environment with three equatorial methyl groups and equally distant (2.49 Å) axial cyanide groups giving rise to the formation of a linear polymeric array by hypervalent bonding. Et₃SnCN has a similar structure.

The coordination environment of germanium in Me₂Ge(CN)₂ is close to tetrahedral; however, the intermolecular N → Ge distances of 3.84 Å indicate a weak association. In Me₂Ge(CN)₂, the angle between equatorial methyl groups is 114°. In Me₃SnCN, the tin atoms are in a TBP environment with three equatorial methyl groups and equally distant (2.49 Å) axial cyanide groups giving rise to the formation of a linear polymeric array by hypervalent bonding. Et₃SnCN has a similar structure.

There is a gradual decrease in the N → Sn distances in going from the exact trigonal-bipyramidal geometry at tin for (CH₃)₃SnN₃ to tetrahedral in (t-Bu)₃SnN₃ (Table 2). However, Me₃SnN₃ (a one-dimensional zigzag polymer attained by 1,1-azide hypervalent bridges) has an N → Sn bond length of 2.386 Å, which is longer than the Sn–N distances in monomeric (t-Bu)₃SnN₃ (2.101 Å) (Table 2) and (t-Bu)₂Sn(N₃)₂ (2.156, 2.141 Å). For triphenyl tin azide, there are two different five-coordinate tin environments formed by 1,3-azide hypervalent bridges giving rise to two different (Ph₃SnN₃)ₙ polymer chains. One has almost planar Ph₃Sn units, while the other shows geometry close to tetrahedral. Thus, triphenyltin azide appears to be along a structural continuum from tetrahedral silicon molecule Ph₃SiN₃ to polymeric lead azide Ph₃PbN₃.

The azide Me₃PbN₃ forms a linear chain polymer with a μ²-N atom symmetrically hypervalent bridging the pentacoordinate lead centers (N–Pb 2.54 Å). The N–Pb–N angle (178.6°) deviates only slightly from the ideal value of 180°. The carbodiimide Me₃SnNCNSnMe₃ forms an infinite helical network, too.

Chloro(diethylamino)dimethyltin consists of discrete dimer molecules, with Sn atoms linked by bridging diethylamino groups. The coordination geometry about the metal atom is a distorted trigonal bipyramid with two C atoms and one N atom in the equatorial plane, and Cl and the second N atom in the axial hypervalent bonding.

Though the crystal structure of monomeric 1-(Ph₃SnCH₂)-1,2,4-triazole contains a tetrahedral tin atom with very weak intramolecular N² → Sn distance 3.000 Å, the molecular structure of 1-(BrPh₂SnCH₂)-1,2,4-triazole consists of two independent cyclic dimers (10-membered cycles), formed by N⁴ → Sn coordinations. Parameters for hypervalent fragments of TBP tin atoms: N⁴ → Sn = 2.463 and 2.474 Å, Sn–Br = 2.633 and 2.641 Å, N⁴ → Sn–Br = 170.5 and 171.8°. On replacing the Br atom by I, the 1-(Ph₂SnCH₂)-1,2,4-triazole obtained is a tetrameric cyclic species (20-membered ring), arising from N⁴ → Sn interactions. There are two distinct trigonal-bipyramidal

tin environments per tetramer with hypervalent fragments: N$_4$ → Sn = 2.36 and 2.45 Å, Sn–I = 2.944 and 2.856 Å, N$_4$ → Sn–I = 174.1 and 171.8°.81.

Attempts to prepare 1 : 1 and 1 : 2 adducts of SnPh$_2$Cl$_2$ with pyrazine (Pyz) by varying the acid-to-base ratio leads exclusively to the formation of an adduct having the bulk composition SnPh$_2$Cl$_2$ · 0.75 Pyz. It has a structure composed of layers in which zigzag polymeric chains, (SnPh$_2$Cl$_2$ · Pyz)$_n$, with six-coordinate tin, alternate with layers containing noninteracting molecules of (SnPh$_2$Cl$_2$)$_2$ · Pyz with five-coordinate tin.82 The data for the hypervalent fragments are: N → Sn = 2.783, 2.961 Å, Sn–Cl = 2.404, 2.379 Å and N → Sn–Cl = 166.7° and 166.2°.

Whereas germanes Ge(NSNR)$_4$ (R = t-Bu, TMS) are monomeric in solution, the $^{119}$Sn NMR data suggest that stannane Sn(NSNBu-t)$_4$ (4) and analogous bis- and tris(sulfurdiimido)tin compounds are associated in solution. The $\delta^{119}$Sn value (−624.0 ppm) of 4 falls in the typical range for hexacoordinated tin atoms.85,86 The structure in the solid state must be similar to that in solution, since the solid state $^{119}$Sn
CP/MAS NMR spectrum reveals an isotropic $\delta^{119}\text{Sn}$ value of $-604.0$ ppm\textsuperscript{83}. The increase of the coordination number at the tin atom in 4 is caused by intermolecular association via the free electron pairs at the nitrogen atoms of the hypervalent $\text{N} \rightarrow \text{Sn} - \text{N}$ systems.

\end{array}
\end{equation}

B. O $\rightarrow$ M Coordination

The tendency for tetrahedral main-group 14 elements to expand the coordination sphere enhances on increasing the nuclear number. Whereas silanole molecules are incorporated in associates by hydrogen bonding, for germanoles an intermolecular O $\rightarrow$ Ge coordination is also characteristic\textsuperscript{87}.

The presence of oxygen donor atoms in monodentate ligands promotes higher coordination numbers of group 14 elements, often leading to stabilization of associates in the solid state. Usually, organotin hydroxides are associated by strong intermolecular O $\rightarrow$ Sn bond and diverse oligomeric and polymeric structures are known\textsuperscript{88–90}. The triorganotin hydroxides Et$_3$SnOH\textsuperscript{91} and Ph$_3$SnOH\textsuperscript{92} crystallize in a zigzag chain structure with the tin atoms being pentacoordinated. The hydroxide groups are located in the axial positions and the hypervalent fragments O $\rightarrow$ Sn are slightly unsymmetrical with Sn–O distances ranging from 2.15 to 2.29 Å. In contrast, the sterically overcrowded [(t-Bu)$_2$Sn(OH)X]\textsubscript{2} (X = F, Cl, Br\textsuperscript{93} and OH\textsuperscript{94}) adopt a dimeric structure and trimesityltin hydroxide\textsuperscript{95} is monomeric in the solid state and the Sn–O bond length amounts to 1.999 Å.

Multinuclear solid- and solution-state NMR investigations of monomer HO(CH$_2$)$_n$SnCl$_3$ ($n = 3–5$) revealed a coordination behavior depending on both the length of the alkyl chain and the solvent. In a noncoordinating solvent, the compounds with three and four carbon atoms between the tin and the hydroxy group ($n = 3, 4$) show exclusively intramolecular HO $\rightarrow$ Sn coordination, resulting in five- and six-membered ring structures, respectively (Section VII.A). With five carbon atoms ($n = 5$), the corresponding intramolecular coordination leads to an unstable seven-membered ring, resulting in intermolecular coordination in the solid state, which is too strong for a CD$_2$Cl$_2$ solvent to break\textsuperscript{96}. The crystal structure of the ($n = 5$) alcohol reveals a polymeric structure that arises from significant intermolecular HO $\rightarrow$ Sn interactions of 2.356 Å. The tin atom is five-coordinate and exists in distorted trigonal-bipyramidal geometry with the oxygen and one of the chlorine atoms defining the axial hypervalent positions\textsuperscript{96}.

The structures of tin alkoxides Sn(OR)$_4$ (R = alkyl, aryl) were extensively investigated and were the subject of a recent review\textsuperscript{97}. As an important conclusion it was pointed out that the degree of association within these compounds decreases with an increasing steric demand of the alkoxy ligands; e.g. Sn(BOBu-$_t$)$_4$\textsuperscript{98,99} is a monomer whereas [Sn(OPr-$_t$)$_4$ $\cdot$ i-PrOH]\textsuperscript{98,100} is a dimer.

In contrast, structural information on organotin alkoxides R$_n$Sn(OR$^1$)$_{4-n}$ (R, R$^1$ = alkyl, aryl; $n = 1–3$) are rather limited. In the structure of Me$_2$SnOMe, almost planar trimethyltin groups are linked by two methoxy ligands forming infinite one-dimensional zigzag chains with nearly ideally trigonal-bipyramidal coordinated tin atoms (cf 5)\textsuperscript{101}. In [Ph$_3$SnOBu-$_t$ $\cdot$ i-BuOH] the tin atom exhibits a distorted trigonal
bipyramidal configuration 6 (O → Sn–O 173.5°) with the isobutoxy ligand being more strongly bonded to tin (2.066 Å) than isobutanol (2.549 Å)\(^{102}\). Isopropyltin triisopropylate contains a dimer 7 with both tin atoms possessing an almost ideal trigonal bipyramidal configuration\(^{103}\).

Organotin carboxylates have been the subject of numerous investigations and more than 400 X-ray crystal structure analyses have been reported to date. Some representative examples of the simplest coordinated organotin carboxylates can adopt one of the two idealized structure types: as intramolecularly bidentate giving rise to a distorted trigonal-bipyramidal coordination geometry (Sections VII.A and X.B.2a), and as a linear polymer formed by unsymmetrical bridging carboxylate groups connecting TBP configurated tin centers with two oxygens in the axial positions. The ideal tetragonal structure of triorganotin carboxylates without secondary interactions was only observed with aromatic carboxylic acids or with bulky substituents at tin. The structural chemistry of organotin carboxylates was thoroughly reviewed by Tiekink\(^ {104}\) and Jurkschat\(^ {65}\).

Reaction of \((n\text{-Bu})_2SnO\) with thiophene glyoxylic acid yields the tetrabutylbis(thiophene glyoxylate)distannoxane which crystallizes as the distannoxane dimer \([((n\text{-Bu})_2SnO_2CC(O)C_4H_3S)_2O]_2\). Determination of the crystal structure of the compound reveals the presence of two different environments for tin and two distinct carboxylate groups; one of them bonds to the six-coordinate tin atom via a carboxylate and keto oxygen atom to form a five-membered chelate ring, whereas the other carboxylate group forms a unidentate bridge (via one oxygen atom only) across the six-coordinate and five-coordinate tin centers\(^ {64}\).

The trimethyltin thiophene-2-carboxylate\(^ {105}\) propagates by glides to give rise to zigzag chains. The furan-2-carboxylate\(^ {106}\) and substituted benzoates\(^ {107}\) propagate by twofold screw axes to form stretched helical chains. Trimethyltin acetate and trimethyltin trifluoroacetate\(^ {108}\) propagate by glides to give rise to zigzag chains. The intramolecular and intermolecular O → Pb distances in trimethyllead acetate amount to 2.327 and 2.555 Å\(^ {109}\).

In solution, the tin acetates CH\(_3\)COO(CH\(_2\))\(_n\)SnCl\(_3\) (\(n = 3–5\))\(^ {110}\) exist as a mixture of a monomer with intramolecular coordination (Section VII.A) and an oligomer with intermolecular coordination in fast equilibrium on the \(^1H\), \(^{13}C\) and \(^{119}Sn\) NMR time
scales. The oligomer is the cyclodimer with carbonyl coordination, as found in an X-ray diffraction analysis of the \((n = 4)\) ester\(^{110}\).

The \(^{119}\)Sn cross polarization-magic angle spinning NMR spectrum of bis[1,3-bis(3-oxapentamethylene carbamoylthioacetato)-1,1,3,3-tetraethyl-1,3-distannoxane] consists of two resonances (\(\delta = -152, -202\) ppm), implying the existence of two five-coordinate tin sites in the centrosymmetric dimer. The crystal structure shows two tin atoms in \(cis\)-\(C_2\), trigonal-bipyramidal coordination\(^{111}\). The \([N,N\text{-dimethylthiocarbamoylthio})\) acetato\\(\text{trimethyltin}\)\(^{112}\) forms a polymer by translations and forms more of a zigzag than a helical chain.

Organotin compounds with intermolecular S\(=\)O \(\rightarrow\) Sn or Se\(=\)O \(\rightarrow\) Sn interactions are relatively rare and only a few single-crystal X-ray crystal structure analyses have been reported. Early examples of coordination are the trimethyltin sulfinites \(\text{Me}_3\text{SnO}_2\text{SR} (R = \text{Me, CH}_2\text{C}≡\text{CH})^{113–115}\) and the corresponding selenates \(\text{R}_3\text{SnO}_2\text{SeR} (R = \text{Me, Ph})^{116–117}\).

The tin sulfite \(\text{Ph}_3\text{SnO-}\text{S(O)-OSnPh}_3\) is monomeric in solution but forms polymeric chains in the solid state with both tetra- and pentacoordinate tin atoms\(^{118}\). In the case of the pentacoordinate tin atoms forming polymeric chains, the axial O \(\rightarrow\) Sn–O angle is 176.9° and the axial bonds are 2.264 and 2.252 Å, which are significantly longer than the sum of covalent radii. These crystal structures are very similar to that of \(\text{Me}_3\text{SnO-}\text{Se(O)-OSnMe}_3\)\(^{119}\) which, however, crystallizes with one equivalent of water\(^{119}\). The crystal structure of \(\text{Ph}_3\text{SnOSO}_2\text{SnPh}_3\) resembles that of the carbonates \(\text{R}_3\text{SnO-}\text{C(O)-OSnR}_3\) with respect to the presence of both tetra- and pentacoordinate tin atoms, and polymeric chains are formed by pentacoordination of tin atoms through O \(\rightarrow\) Sn–O linkages\(^{120}\).

The triorganotin phosphinates \(\text{Me}_3\text{SnO}_2\text{PMe}_2\)\(^{121}\), \(\text{Me}_3\text{SnO}_2\text{PCl}_2\)\(^{121}\) and \(\text{Bu}_3\text{SnO}_2\text{PPh}_2\)\(^{122}\) self-assemble in the solid state to give polymeric helical chain structures with pentacoordinated tin atoms. In contrast, dithiophosphorus acid derivatives show a higher tendency to function as chelating rather than bridging ligands\(^{123,124}\).

The crystal structure of the complex of diphenyltin dichloride with propylenediphosphonate consists of polymer chains with bridging bidentate ligands and an octahedral tin environment containing two types of phosphoryl fragments\(^{125–127}\). All of the \(\text{R}_2\text{SnX}_2\) adducts have \(\text{trans-R}_2\text{SnX}_2\text{O}_2\) geometries of octahedral tin coordination. The main Sn–Cl and Sn–O bond distances in octahedral coordination of polymeric diphosphoryl complexes of organotin halides are comparable. The C–Sn–C angles are significantly smaller (154–164°) than 180°.

Attempts to prepare organotin derivatives of phosphorus acids usually resulted in amorphous powders unsuitable for X-ray diffraction\(^{123}\). However, the crystal structure analysis of one representative, namely \((\text{Me}_2\text{Sn})_3(\text{PO}_3)_2·8\text{H}_2\text{O}\), was reported\(^{128}\). The organotin phosphate is built up by fused eight-membered Sn\(_2\)O\(_4\)P\(_2\) rings with alternating \(\text{Me}_2\text{Sn}\) and \(\text{Sn}-\text{O}\) bond distances in octahedral coordination of polymeric diphosphoryl complexes of organotin halides are comparable. The C–Sn–C angles are significantly smaller (154–164°) than 180°.

Compounds \(8\)\(^{129}\) and \(9\)\(^{130}\) are associated as dimers via O \(\rightarrow\) Sn interactions: there are intermolecular O \(\rightarrow\) Sn distances (2.327 and 2.587 Å) approximately \(\text{trans}\) to \(S^2\) (angle 150.6°) and N (angle 146.92°) with a symmetrical distannoxane Sn\(_2\)O\(_2\) unit. In addition, there are intramolecular O \(\rightarrow\) Sn bonds (2.679 Å with HOCH\(2\)CH\(_2\)S ligands in \(8\)) and transannular N \(\rightarrow\) Sn bonds (2.224 Å in \(9\)) and the tin coordination is raised to 6. Only one signal at 28.7 ppm is observed in the \(^{119}\)Sn NMR spectrum of \(8\), which is within the range for the four-coordinated tin nucleus. Therefore, the structure of \(8\) in solution is
different from that observed in the solid state and there are no intermolecular \( O \rightarrow Sn \) interactions in solution\(^{129}\).

The reaction of the dimethyltin(IV) cation with pyridoxine [3-hydroxy-4,5-bis(hydroxymethyl)-2-methylpyridine, PN] has been investigated in ethanol–water (80 : 20 v/v) containing \( NO_3^- \), \( NO_3^- \) and \( Cl^- \), \( NO_3^- \) and \( MeCO_2^- \) or \( Cl^- \) and \( MeCO_2^- \) ions in various mole ratios\(^{131}\). In each dimeric unit of 10 and 11 (Table 3) the tin atom is coordinated to two methyl groups, the phenolic O atom, the O atoms of two deprotonated \( CH_2OH \) groups and the O atom of a nondeprotonated \( CH_2OH \) group. In 10 the units are connected in a polymeric structure via the O of a deprotonated \( CH_2OH \) group of each PN–H. In compound 11 the coordination polyhedron of the tin atom is completed within the dimeric unit by water molecules which thus prevent the polymerization found in 10. The C–Sn–C angle is slightly wider in 11 (159.9°) than in 10 (143.8°), probably because the O → Sn distance of 2.466 Å in 11 is much shorter than the O → Sn distance of 2.802 Å in 10. In 12 the crystal contains dimeric \([SnMe_2(H_2O)(PN-2H)]_2\) units in which the dideprotonated ligand coordinates as in 10 and water.

The \( R_2(X)SnOSn(X)R_2 \) species associates have structure considerably more confusing (monomers have appeared only for the compound with \( R = 2,4,6\)-tris(trifluoromethyl) phenyl and \( X = Cl\))\(^{132}\). A characteristic feature of symmetric tetraorganodistannoxanes in the solid state is their dimerization, resulting in the so-called ladder-type arrangement, which contains a central planar Sn2O2 four-membered ring. The \([(t-Bu)_2(F)SnOSn(F)(Bu-t)]_2\) (13)\(^{133}\) and \([(R_2ClSn)_2O)_2\] (\( R = Me, i-Pr, Ph\))\(^{134}\) exhibit a centrosymmetric dimer with a typical ladder-type arrangement. In 13 the terminal Sn$^2-F^5$ distance
(1.981 Å) is almost identical to single bond length whereas \( {\text{F}}^a \rightarrow \text{Sn}^2 \) and \( \text{Sn}^1 \rightarrow {\text{F}}^a \) distances are much longer (2.196 Å and 2.177 Å, respectively). The \( {\text{F}}^b \rightarrow \text{Sn}^1 \) distance of 3.656 Å is too large to be considered as an interaction.

In solution, \textbf{13} exhibits a unique valence tautomerism as evidenced by \( ^{19}\text{F} \) and \( ^{119}\text{Sn} \) NMR spectroscopy; for example the \( ^1J({^{117/119}\text{Sn}}-{^{19}\text{F}}) = 2442/2335 \) Hz satellites are

averaged couplings for the Sn²–Fᵃ and Sn²–Fᵇ bond pairs. The two smaller non-averaged couplings of 874/834 Hz and 743/709 Hz are assigned to the pairs Sn¹–Fᵃ and Sn¹–Fᵇ, respectively. These and other data are explained by the equilibrium between the valence tautomers with the averaged structure 13a as a transition state. The valence tautomer interconversion of 13 represents a unique example where, for the first time, the ‘motion of electron density’ in a hypervalent system becomes visible by NMR spectroscopy.

Of the [R₂(Cl)SnOSn(Cl)R₁₂]₂-type compounds 14–16, selected interatomic Sn–Cl distances for 15 are listed in Table 4.

There is a substantial difference between the structures found for the symmetric and asymmetric \((R \neq R^1)\) compounds. In the symmetric compounds \((14)\) one Cl atom forms a symmetric bridge and the other is essentially terminal. This has the consequence that in the symmetric \([(R_2SnCl)_2O]_2\) species both Sn atoms are five-coordinate and trigonal-bipyramidal. However, in the asymmetric compounds \((15)\) both Cl atoms are involved in weak, but significant interactions with the endocyclic Sn atom. Ladder compounds containing \(t\)-Bu substituents at tin may be isolated in the solid state as discrete molecular species \([((t\text{-}Bu)_2(Cl)SnOSn(Cl)R_2)]_2\), which may be regarded as the 1 : 2 adduct \([(t\text{-}Bu)_2SnCl_2(R_2SnO)(t\text{-}Bu)_2SnCl_2)]_2\) \((16)\). In solution this adduct is labile and undergoes some dissociation, whose extent depends on the nature of the R group.

Attempts to form a ladder species, \([(t\text{-}Bu)_2SnCl_2)((t\text{-}Bu)_2SnO)(t\text{-}Bu)_2SnCl_2]\), where all four tin atoms carry \(t\)-Bu substituents, were unsuccessful. Formation of that ladder species would require the tin atoms in the central \((t\text{-}Bu)_2SnO_2\) moiety to be able to become six-coordinate. Apparently, the \(t\)-Bu groups reduce the Lewis acidity at tin or they are sterically overcrowded to such an extent that six-coordination is not possible. Instead, there is evidence for the 1 : 1 adduct \([(t\text{-}Bu)_2SnCl_2)((t\text{-}Bu)_2SnO)]_2\), in which the tin atoms are all five-coordinate.

The formation of a ladder-type 1 : 2 associate, which contains a central planar Sn\(_2\)O\(_2\) four-membered ring (e.g. \((17)\)), and more complete symmetric species\(^{140-146}\) are often observed for diorganotin alkoxides.

The dihalogenated 1,2,5-oxaphosphastannolane dimerizes as a result of an intermolecular O \(\rightarrow\) Sn coordination to give a diastereomeric mixture\(^{147}\); the structure of one of them \((18)\) is shown. As a result of both inter- and intramolecular interactions the coordination

c Fragment of catena-(hexakis(µ₂-cyano)-diaqua-dodecamethyliron-tetralead).

dimetallic structure 18 can be described as distorted octahedra with trans-angles of 173.9° for O → Sn−Cl and 161.78° for O → Sn−O. The almost equal intermolecular dative O → Sn and covalent Sn−O bond lengths of 2.140 Å and 2.147 Å, respectively, are shorter than the intramolecular O → Sn distance of 2.204 Å147.

Only few examples of self-organized organolead compounds with oxygen-based donors were reported to date (Table 5). Lead hydroxide Ph₃PbOH92 is isostructural with its tin analogue and forms zigzag chains in which planar Ph₃Pb fragments are linked by hydroxide groups. In the unsymmetrical O → Pb−O fragment the oxygen–lead bond lengths amount to 2.44 and 2.37 Å.

Catena-[µ₂-acetoxy]-acetoxydiphenyllead(IV) (19) is among the few structurally characterized hypervalent hexacoordinate organolead acetates. The latter forms a polymer via intermolecular O → Pb interactions152.

C. Hal → M Coordination

In the condensed phase Me₃SiF molecules show no intermolecular interactions, while the same germanium derivatives are associated as a dimer due to intermolecular F → Ge87 coordination. According to the tendency for tetrahedral main-group 14 elements to expand the coordination sphere, organotin fluorides show a strong tendency to associate in the solid state and even in triorganotin fluorides the tin atom is five-coordinate153,154. A common feature of this class of compounds in the solid state is coordination expansion of the tin atom due to hypervalent interaction, which in turn often results in formation of polymeric materials.

Trimethylfluorostannane is probably a chain-type polymer155 containing five-coordinate tin. Solid state ¹¹⁹Sn NMR studies have confirmed five coordination for Me₃SnF, as well as for (i-Bu)₃SnF and Ph₃SnF66. Two identical Sn−F distances of 2.146 Å for the hypervalent fragment F → Sn−F in the axial positions of a symmetrical trigonal bipyramid was observed for Ph₃SnF156. For the unsymmetrically substituted triorganotin fluoride Me₂PhSnF157 the tin fluoride adopts a structure with only slightly different Sn−F distances of 2.179 and 2.162 Å and F → Sn−F angle of 179.4°. An unsymmetrical structure with Sn−F distances of 2.051 and 2.303 Å was reported for the sterically overcrowded (c-Hex)₃SnF158. For comparison, the Sn−F single bond distance in monomeric [(SiMe₃)₃C]₂PbSnF₁₅₉ and Mes₃SnF₉₅ is 1.96 Å in the solid state and it contains four-coordinate tin, presumably because the bulky organyl substituent prevents hypervalent bridging.
In contrast, difluorostannanes \( \text{R}_2\text{SnF}_2 \) (\( \text{R} = \text{Me}, \text{n-Bu}, \text{Ph} \)) show strong intermolecular \( \text{F} \rightarrow \text{Sn} - \text{F} \) hypervalent bridges and consequently are almost insoluble in organic solvents\(^{66}\). The poor solubility of organylfluorostannanes has largely restricted their study to investigations of solid compounds. For example, \( \text{Me}_2\text{SnF}_2 \) is a sheetlike polymer\(^{160}\) containing six-coordinate tin. Vibrational and \(^{119}\text{Sn} \) Mössbauer spectroscopies imply that \( \text{MeSnF}_3 \) contains both bridging and terminal fluorides such that the tin is six-coordinate\(^{161}\).

Although \( \text{Cl} \rightarrow \text{Sn} \) bonds are weaker than \( \text{F} \rightarrow \text{Sn} \) bonds they are strong enough to give hypervalent association of triorganotin chlorides in the solid state\(^{5,90,162,163}\). An example of \( \text{Sn}_3\text{Cl} \) crystallizing as a linear chain polymer, having one short \( \text{Sn} - \text{Cl} \) distance of \( 2.387 \, \text{Å} \), and one long \( \text{Cl} \rightarrow \text{Sn} \) distance of \( 3.531 \, \text{Å} \), was observed\(^{164}\). \( \text{Me}_3\text{SnCl} \)\(^{162,163}\) forms a zigzag chain, with \( \text{Sn} - \text{Cl} \) distances of \( 2.430 \, \text{Å} \) and \( 3.269 \, \text{Å} \), and \( \text{Sn} - \text{Cl} \) angle of \( 150.5^\circ \). In contrast, \( \text{Ph}_3\text{SnCl} \)\(^{165}\) does not self-associate in the solid state and consists of discrete tetrahedral molecules.

Compounds with the general formula \( \text{R}_2\text{SnCl}_2 \) are commonly found to dimerize via hypervalent \( \text{Cl} \rightarrow \text{Sn} - \text{Cl} \) bridges\(^{166-170}\). It is significant that the intermolecular \( \text{Cl} \rightarrow \text{Sn} \) interactions of \( 3.54 \, \text{Å} \) (\( \text{R} = \text{Me}^{171} \)), \( 3.483 \, \text{Å} \) (\( \text{Et}^{172} \)), \( 3.308 \, \text{Å} \) (\( \text{i-Pr}^{173} \)), \( 3.514 \, \text{Å} \) (\( \text{n-Bu}^{174} \)), \( 3.770 \, \text{Å} \) (\( \text{Ph}^{175} \)), \( 3.332 \, \text{Å} \) (\( \text{E}_{\text{t}}^{176} \)), \( 3.482 \, \text{Å} \) [\( \text{Ph(Me)SnCl}_2 \)]\(^{177}\) are less than the sum of van der Waals radii. It is noteworthy that there are no intermolecular \( \text{Cl} \cdots \text{Sn} \) contacts > \( 4.0 \, \text{Å} \) in two compounds, i.e. when \( \text{R} = 2\text{-PhC}_6\text{H}_4^{178} \) and \( \text{R} = \text{t-Bu}^{173} \) which contain the most bulky tin-bound substituents of the compounds listed above.

Hypervalent \( \text{Cl} \rightarrow \text{Sn} - \text{Cl} \) bridges are also typical for pentacoordinate tin atoms. For example, the crystal structure of \( \text{MeOOCCH}_2\text{CH(COOMe)CH}_2\text{Sn(S}_2\text{CNEt}_2)\text{Cl}_2 \)\(^{168,179}\) and \( \text{MeSn(Ar)Cl}_2 \)\(^{170}\) comprise dimeric pairs of molecules bridged by weak intermolecular \( \text{Cl} \rightarrow \text{Sn} \) interactions. The \( \text{Cl} \rightarrow \text{Sn} \) distances in \( 20 \) (\( 2.475 \, \text{Å}^{179} \)), \( 21 \) (average \( 3.869 \, \text{Å}^{170} \)) and in \( \text{MeSn(Ar)Cl}_2 \) (\( \text{Ar} = 3\text{-methyl-4-nitropyridine-N-oxide} \)) (\( 3.934 \, \text{Å}^{180} \)) are longer than in most comparable structures\(^{168,169,181}\). The \(^{119}\text{Sn} \) NMR resonance (\( -285.7 \, \text{ppm} \)) for \( 21 \) suggests that it possesses a five-coordinate structure in solution\(^{170}\).

The structure of \( \text{MeOOCCH}_2\text{CH(COOMe)CH}_2\text{Sn(S}_2\text{CNEt}_2)\text{Cl}_2 \), the only other previously characterized \( \text{RSn(S}_2\text{CNEt}_2)\text{Cl}_2 \) compound, is very different from that of \( 21 \) as the \( \text{MeOOCCH}_2\text{CH(COOMe)CH}_2 \)- ligand is bidentate, giving rise to a monomeric, six-coordinate structure (Section X.B) in which there are no \( \text{Cl} \cdots \text{Sn} \) bridges\(^{182}\).

Compound \( 22 \) exhibits a distorted trigonal-bipyramidal geometry at both Sn atoms. The intermolecular \( \text{Cl} \rightarrow \text{Sn} \) bond of \( 3.116 \, \text{Å} \) is considerably longer than the axial \( \text{Sn}^2 - \text{Cl} \) bond (\( 2.420 \, \text{Å} \)), which in turn is longer than the equatorial \( \text{Sn}^2 - \text{Cl} \) bond (\( 2.370 \, \text{Å} \))\(^{183}\). In contrast, the bromodimethyl(\( N\text{-methylpyrroolidin-2-one-O} \)tin(IV)-di-\( \mu \)-bromo-bromodimethylin(IV), \( 23 \), contains two Sn atoms in the asymmetric unit, the Sn\(^1\) complexed by \( N\text{-methylpyrroolidin-2-one} \)exhibiting a hexacoordinated arrangement while Sn\(^2\) is pentacoordinated with hypervalent fragments possessing the following parameters: \( \text{Br} \rightarrow \text{Sn}^1 = 3.584 \, \text{Å}, \, \text{Sn}^1 - \text{Br} = 2.508 \, \text{Å}, \, \text{Br} \rightarrow \text{Sn}^1 - \text{Br} = 178.0^\circ \) and \( \text{Br} \rightarrow \text{Sn}^2 = 3.712 \, \text{Å}, \, \text{Sn}^2 - \text{Br} = 2.506 \, \text{Å}, \, \text{Br} \rightarrow \text{Sn}^2 - \text{Br} = 169.7^\circ \)\(^{184}\).

Triorganolead halides are usually associated in the solid state, which was confirmed by X-ray crystallography\(^{185-188}\). Usually, the lead atom is pentacoordinated with the halogen atoms located at the axial positions of a trigonal bipyramid, forming infinite chains with unsymmetrical \( \text{X} \rightarrow \text{Pb} - \text{X} \) links. The two lead–halide distances in a given compound differ significantly. Thus in \( \text{Me}_3\text{PbI} \) the lead–iodine distances amount to \( 3.038 \) and \( 3.360 \, \text{Å} \)\(^{186}\), whereas the lead–bromine distances are \( 2.852 \) and \( 3.106 \, \text{Å} \) in \( \text{Ph}_3\text{PbBr}^{185} \), and \( 2.885 \) and \( 2.985 \, \text{Å} \) in \( \text{BnPh}_2\text{PbBr}^{187} \). All structures reported show a linear \( \text{X} \rightarrow \text{Pb} - \text{X} \) fragment\(^{185,186}\).
The Pb—Br bond (2.696 Å) has been shortened relative to the terminal bond (2.852 Å) and the bridging (3.106 Å) Pb—Br bonds in the parent Lewis acid, which adopts a helical chain structure\textsuperscript{189}. The molecule Ph\textsubscript{2}PbCl\textsubscript{2}\textsuperscript{190} forms chains in which an octahedral Pb atom is linked by Cl bridges.
D. Other X → M Coordination

For hypervalent compounds the S → Sn interactions are less known than O → Sn ones. Generally, a tin center in an unassociated diorganotin dithiolate is coordinatively unsaturated and will coordinate, at least in the solid state, with available internal or external donor centers, unless other factors, such as steric hindrance, are operating. For solid diorganotin 1,2-ethanedi(thiolates), R₂Sn(EDT), only thiolato S atoms are available for intermolecular hypervalent coordination, with the formation of SSnSSn rings. The number and strength of the S → Sn interactions depend on the R group, e.g. the intermolecular S → Sn bond length in pentacoordinate Me₂Sn(EDT) is 3.18 Å, and in hexacoordinate Bu₂Sn(EDT) 3.69 Å. There is a single long intermolecular S···Sn separation of 3.885 Å in Ph₂Sn(EDT), which is within the sum of the van der Waals radii of Sn and S.

The compound (t-Bu)₂Sn(DMIT) is unassociated. The tin center in solid PhMeSn(DMIT) (24a) is five-coordinate with a trigonal-bipyramidal geometry: the molecules are linked into spiral chains via intermolecular S(thione) → Sn interactions (Table 6). This was confirmed by the single δ¹¹⁹Sn value (94.9 ppm) in the solid state ¹¹⁹Sn NMR spectrum.

![Diagram of compounds](image)

Compound Me₂Sn(DMIT) (24b) and orthorhombic Et₂Sn(DMIT) (24c) are linked into chains as a result of intermolecular S(thione) → Sn interactions. The tin centers are pentacoordinate with distorted TBP geometries. The intermolecular S → Sn bonds of 3.001 and 2.960 Å in the two independent molecules of 24b, and 3.008 Å in 24c at 150 K (3.037 Å at 298 K), are considerably longer than the covalent Sn bonds to the dithiolato Sax andSeq atoms between 2.440 and 2.523 Å (Table 5). As expected, the axial dithiolato — tin bond of 2.523 Å is longer than the equatorial bond, 2.459 Å. The distortions from ideal trigonal-bipyramidal arrays in 24a–c are not the result of the presence of the chelate, since the chelate bite angles are near 90° in all cases.

*aE = O.  
bE = S.  
cTwo independent molecules; see footnote in Table 6.*

In the case of Me₂Sn(DMIO) (25a) intermolecular associations involve both a carbonyl O and a thiolato S atom and a six-coordinate tin (Table 7), and again a SSnSn ring is formed 191.

The two independent molecules of monoclinic Et₂Sn(DMIT) 25b have quite different arrangements: tin atoms in molecule A (Table 7) form two relatively weak intermolecular thione S → Sn bonds of 3.567 and 3.620 Å, with the formation of sheets, while those in molecule B form a similar bond, S → Sn = 3.555 Å to give chains, with a much longer contact, S···Sn = 3.927 Å to another chain. The latter is only ca 0.03 Å less than the van der Waals radii sum for Sn and S (Table 1).

The geometries in the six-coordinate species, 25a and 25b, are also far from regular: even a severely distorted octahedral description appears inappropriate. The DMIO derivative, 25a, forms a honeycomb network due to a combination of S → Sn and O → Sn intermolecular interactions and the rings are formed from six molecules 191.

Examples of association resulting from intermolecular sulfur → organolead hypervalent interactions are rare and compounds such as Me₃PbSMe and Ph₃PbSPh are monomeric in the solid state 199. The cyclic diorganodithiolate 2,2-diphienyl-1,3,2-dithiaplumbolan 200 self-assembles in the solid state via intermolecular sulfur → tin interactions into a one-dimensional polymeric array. The intramolecular S → Pb bond lengths amount to 2.52 and 2.49 Å, and the intermolecular S → Pb distances are 3.55 Å.

Hypervalent compounds with coordinative phosphorus → tin bonds are rare. An intermolecular P → Sn coordination in Me₂ClSnCH₂CH₂PPh₂ and its bromo-substituted analogue was suggested based on NMR and ¹¹⁹Sn Mössbauer spectroscopic data 201,202. The X-ray crystal structure analyses showed pentacoordinate tin atoms with the phosphorus and the chlorine atoms located in axial positions 203. The P → Sn distance amounts to
IV. PENTACOORDINATE ANIONIC COMPOUNDS

A. Intermolecular Complexes

1. Tetraorganotin and tetra- and triorganogermainium derivatives

Tetraorganogermanes, -stannanes and -plumbanes bearing four M–C bonds and having no donor atoms in the organic moiety have been known to be usually reluctant to form pentacoordinate anionic complexes\textsuperscript{1,4,6.8.205}. However, in the case of the lithium—tin exchange reaction, NMR evidence for the formation of the intermediate species Me\textsubscript{5}Sn– and Ph\textsubscript{5}Sn– was presented\textsuperscript{206}. With the highly electronegative trifluoromethyl group as a substituent at germanium, the Lewis acid character of this atom is conserved. As a result, the reactions of (CF\textsubscript{3})\textsubscript{n}GeX\textsubscript{4–n} (X = Hal, n = 1–4) with fluoride ions (as KF, NaF or NH\textsubscript{4}F) in aqueous or acetonitrile solutions give pentacoordinate and hexacoordinate anionic complexes\textsuperscript{207,208}. Bulky CF\textsubscript{3} groups decrease the germanium capacity for hexacoordination. Consequently, octahedral fluorine complexes have been observed upon fluoride addition to CF\textsubscript{3}GeF\textsubscript{3} or (CF\textsubscript{3})\textsubscript{2}GeF\textsubscript{2}, whereas the derivatives containing four or three CF\textsubscript{3} groups yield mostly pentacoordinated monoanions \textsuperscript{26} and \textsuperscript{27} (equations 1 and 2).

\[
\begin{align*}
\text{CF}_3\text{Ge}^{+} + \text{F}^- & \rightarrow \text{CF}_3\text{GeF}^- \quad (26) \\
\text{H}_2\text{O}, \text{F}^- \rightarrow \text{CF}_3\text{GeF}^- & \rightarrow \text{CF}_3\text{GeF}_{2}^{2-} \quad (27)
\end{align*}
\]

\[
\begin{align*}
\text{CF}_3\text{GeCl}^{+} + \text{F}^- & \rightarrow \text{CF}_3\text{GeF}^- \rightarrow \text{CF}_3\text{GeF}_{2}^{2-} \quad (28)
\end{align*}
\]

In aprotic solvents, however, both (CF\textsubscript{3})\textsubscript{4}Ge and (CF\textsubscript{3})\textsubscript{3}GeCl react with excess of fluoride ion to give octahedral species \textsuperscript{28} and \textsuperscript{29} which are stable only in the absence of moisture\textsuperscript{208}. According to \textsuperscript{19}F NMR spectroscopy, the monoanions \textsuperscript{26} and \textsuperscript{27} have in solution the TBP structures, with the fluorine atoms occupying the apical positions. The structure of anion \textsuperscript{27} in the complex [Me\textsubscript{4}N][((CF\textsubscript{3})\textsubscript{3}GeF\textsubscript{2})], obtained by treatment of Na[(CF\textsubscript{3})\textsubscript{3}GeF\textsubscript{2}] with Me\textsubscript{4}NCl in ethanol, provides an example for the almost ideal TBP structure (F–Ge–F 177.4°) with three equatorial trifluoromethyl groups\textsuperscript{208}. The axial Ge–F bonds (1.81 Å) are significantly longer as compared to those determined for the tetrahedral derivatives (1.74 Å in Me\textsubscript{2}GeF\textsubscript{3}\textsuperscript{9}), whereas the averaged equatorial C–Ge distance (1.98 Å) is not essentially different from that of 1.99 Å in (CF\textsubscript{3})\textsubscript{4}Ge\textsuperscript{9}.

2. Triorganostannates

The data on stable pentacoordinate anionic organylhalo-germaine and -lead complexes with halide ions are rather limited, in particular on those where the structure was determined by X-ray investigation (see the reviews\textsuperscript{7,8} and references cited therein). On the contrary, the strong Lewis acidity of organylhalostannanes toward halide ion has been the subject of study for many years\textsuperscript{8,209,210}. Moreover, the pentacoordinate anionic tin complexes have attracted attention in recent years as reagents for selective organic syntheses\textsuperscript{211,212}, as well as in host–guest chemistry\textsuperscript{213–217} and as soluble organotin halides for biocides\textsuperscript{8}.

3.065 Å, which is comparable to the P → Sn distance of 3.078 Å in the monomeric, intramolecularly coordinated Me\textsubscript{2}ClSnCH\textsubscript{2}CH\textsubscript{2}CH\textsubscript{2}PPhBu-\textsubscript{t}\textsuperscript{204}. 
The reaction is reversible (equation 3, step a) and, furthermore, a mixture of stannate complexes may undergo disproportionation to establish an equilibrium between homo- and mixed-ligand compounds (equation 3, step b). Moreover, the aryloxy mixed ligand stannates 36–38 are more stable than a 1 : 1 mixture of the corresponding dichloro- and bis(aryloxy)-stannates. Thus, the stability of the TAS stannates with TBP structures is highly affected by the nature of the equatorial organic groups and apical heteroatom substituents.

\[
R_3SnX + TAS^+ Y^- \xrightleftharpoons[\text{a}]{\text{b}} [R_3SnXY]^- \xrightleftharpoons[\text{b(X \neq Y)}]{1/2} 1/2[R_3SnX_2]^- + 1/2[R_3SnY_2]^- \xrightleftharpoons[\text{b(X \neq Y)}]{1/2} R_3SnX + TAS^+ Y^- (36–38)
\]

As judged by NMR investigation, hexacoordinate Sn complexes are not formed by the addition of excess chloride, arylxide or HMPA to the pentacoordinate complexes 30a–32a, 33–35 226.

Analogously, attempts to prepare stable adducts from the reaction of stannates Ph₃SnF₂⁻ or Ph₃Sn(F)Cl⁻ with F⁻, Et₄NCl, HMPA or DMSO were also unsuccessful. However, small changes in the chemical shifts and coupling constants detected by the addition of fluoride ion or DMSO to Ph₃SnF₂⁻ were interpreted as due to the formation of small amounts of the six-coordinate adducts 218.

Nucleophic addition of halides or cyanide to Me₃SnCl leads to a series of salts 30b–d, 39a, 39b and 40 containing trimethyltin anions with a variety of cations (equation 4) 219.

Tetraalkyammonium stannates 30c and 39a obtained in CH₂Cl₂ or CH₃CN solution in 62–71% yield are susceptible to hydrolysis. The more stable potassium 18-crown-6 stannates 30d, 39b and 40, handled for a prolonged time in air, were prepared in quantitative yields in toluene solution.
In some cases anionic complexes can be obtained by the interaction of triorganylhalostannanes with neutral donors. For example, the reaction of Me₃SnBr with HMPA led to formation of the complex [Me₃SnBr₂][Me₃Sn(HMPA)₂] (41) in which both the cation and the anion contain TBP tin atoms.

While stable neutral five-coordinate adducts (Ar₃SnX·L; X = N₃, NCO, NCS; L = various O- and N-donor ligands) are well known (Section V.B), some aliphatic amines react with Ph₃SnN₃ to form the anionic complexes 42a–d, presumably due to the water present in the incompletely dried solvent or ligand (equation 5).

\[
2\text{Ph}_3\text{SnN}_3 + \text{L(H}_2\text{O}) \rightarrow [\text{Ph}_3\text{Sn(N}_3)_2]^- (\text{LH})^+ + \text{Ph}_3\text{SnOH}'
\]

The similar anionic complex [Ph₃Sn(NCS)₂][L₂H] (43a) (L = 1-(salicylideneimino)-2-methoxybenzene) was obtained by the reaction of Ph₃SnNCS and the corresponding ligand (1 : 2) in 95% ethanol. Another case of Ph₃Sn(NCS)₂⁻ formation in the salt [Ph₃Sn(NCS)₂][Et₄N] (43b) was observed on work-up of a reaction mixture derived from the sequential addition to [(PhCO)₂C₃S₅] (dibenzoyl-DIMT) of NaOMe, Ph₂Sn(NCS)₂ and Et₄NBr.

Recently, a series of trifluoroacetates (44a–c) have been described. Unlike other triorganotin carboxylates such as the acetates, which display no discernible Lewis acceptor properties, triorganotin trifluoroacetates form pentacoordinate complexes with neutral and anionic donors. Consequently, the interaction of trifluoroacetic acid, a molar equivalent of di-2-pyridylamine (DPA) yielded stannate 44c instead of the desirable neutral complex. Analogous reaction using a molar equivalent each of trifluoroacetic acid and chlorodifluoroacetic acid gave the mixed stannate [Ph₃Sn(OCOCF₃)(OCOCF₂Cl)][DPAH] (45) as one of the products. The latter is the first example of a triorganostannate having two different carboxylato groups covalently bonded to tin. A similar synthesis of coumarin-3-carboxylato stannate 46 involves the reaction of tetramethylammonium hydroxide, coumarin-3-carboxylic acid and Ph₃SnOH in 1 : 2 : 1 ratio in ethanol.

Some reports demonstrate the utility of the hypervalent species [R₃SnF₂]⁻ as useful reagents and intermediates. In particular, the crystalline stannate [Ph₃SnF₂][Bu₄N] (47) is relatively stable up to 210 °C and is not hygroscopic or undergoes hydration. Recently, its availability as a fluorinating agent was shown for the transformation of PhCH₂Br into PhCH₂F₂ and of gem-bistriflates RCH(OTf)₂ (R = Alk, Ar) into the mono-fluorides RCH(OTf)F₂ and the di-fluorides RCHF₂. Difluoroenoxyisilanes are produced in high yield by catalytic activation of a mixture of CF₃SiMe₃ and an acylsilane by using 47. In turn, enoxysilanes may be effectively alkylated by alkyl bromides in...
the presence of \textsuperscript{47}\textsuperscript{211}. Analogously, the reaction of alkenyl triflates with \textsuperscript{47} catalyzed by Pd(PPh\textsubscript{3})\textsubscript{4} affords regio- and stereospecifically the corresponding alkenylbenzene in excellent yields\textsuperscript{247}. Sulfuration of \textsuperscript{47} with elemental sulfur gives a simple and practical methodology for generating C−S bonds under almost neutral conditions and, in particular, the disulfide PhSSPh was obtained in a quantitative yield\textsuperscript{212}.

\textit{b. Crystal structures.} X-ray crystallographic structures of the pentacoordinate triorgano-stannate complexes \textsuperscript{30d–h}, \textsuperscript{31b}, \textsuperscript{32b–d}, \textsuperscript{33}, \textsuperscript{38}, \textsuperscript{41}, \textsuperscript{42a–c}, \textsuperscript{43a,b}, \textsuperscript{44a–c}, \textsuperscript{45}, \textsuperscript{46}, \textsuperscript{48–52}, including zwitterionic stannates (Section IV.A.6) have been reported. Tables 8–10 list the principal structural parameters for anions \textsuperscript{R\textsubscript{3}SnX\textsubscript{2}}\textsuperscript{−} and \textsuperscript{R\textsubscript{3}SnXY}\textsuperscript{−} in the homo- and mixed-ligand complexes discussed above, which are generally composed of discrete cations and anions. These anions possess a near-TBP arrangement with the organic and electronegative groups occupying the equatorial and apical positions, respectively. In the case of homo-ligand halide complexes (Table 8), near-regular TBP was found for large cations, in particular [K(18-crown-6)]\textsuperscript{+}, {[(Ph\textsubscript{3}PAu)\textsubscript{2}S]\textsubscript{2}Au}\textsuperscript{+} (complexes \textsuperscript{30d}\textsuperscript{219} and \textsuperscript{30h}\textsuperscript{248}, respectively).

Equal anions Ph\textsubscript{3}Sn(NCS)\textsubscript{2}\textsuperscript{−} in both described isothiocyanato complexes \textsuperscript{43a}\textsuperscript{230} and \textsuperscript{43b}\textsuperscript{231} have an almost ideal TBP arrangement about the tin atom regardless of the counterion (Table 9). The TBP structure of the anion Ph\textsubscript{3}Sn(N\textsubscript{3})\textsubscript{2}\textsuperscript{−} in the complex \textsuperscript{42c}\textsuperscript{225} is also close to ideal. In contrast, the axial azide groups in the stannates \textsuperscript{42a} and \textsuperscript{42b} are not equivalent (Table 10), showing that one azide group is acting as a weaker ligand than the other\textsuperscript{229}. This effect is clearly due to the hydrogen bonding in which this weaker donor azide group is involved.

The essentially linear geometry of the X−Sn−X or X−Sn−Y fragment and the significant lengthening of the X−Sn and Y−Sn bonds are consistent with the hypervalent nature of the apical bonds. The Sn−C bond lengths (2.11−2.15 Å) are close to those of the corresponding tetrahedral derivatives with the exceptions of compounds \textsuperscript{30h}\textsuperscript{248}, \textsuperscript{31b}\textsuperscript{221} and \textsuperscript{32d}\textsuperscript{221}, in which these distances are 2.212, 2.235 and 2.193 Å, respectively (Table 8).
The structure of the chlorine-cyanide stannate 39b is unusual in that the strongly nucleophilic cyanide would exhibit N-bonded coordination to Sn rather than a C-bonded orientation. 219

In the case of homo-ligand dihalide complexes, Sn–Hal distances lie generally in the range of 2.57–2.69 Å for dichlorides and 2.73–2.79 Å for dibromides, and the relative lengthenings of these bonds are almost equal (11.5 and 11.3%). Analogously, the Sn–N bond lengths in the anion [Ph3Sn(N3)]− of the complexes 42a–c are longer as compared to those in t-Bu3SnN3 (2.103 Å)26 containing a tetrahedral tin atom. It is noteworthy that in the stannate 42c, in which the Sn–N bonds are equal, their values are intermediate between those found for asymmetric bonding in the protonated derivatives 42a,b. An unusually long Sn–F bond length was found259 for Me3SnF2−. However, this value is associated with the Sn–Cl bonds in Me3SnCl2−. 260

$^k$R$_1$OH = 2-(3′-methylphenyliminomethyl)phenol-O.
$^l$R$_2$OH = 1-(4′-methylphenyliminomethyl)-2-naphthol-O.

The Sn–O distances in the homo-ligand oxystannates 33, 44a–c and 50 (Table 9) increase in the order of ligands OAr < OCOCF$_3$ < ONO$_2$, which is parallel to the decrease in their basicity and donor ability.

The mixed-ligand stannates (Table 10) are especially of interest in the context of the mutual influence of the apical ligands in the hypervalency theory, first developed by Musher. In these compounds the bond lengths with apical ligands differ considerably from those of the corresponding homo-ligand stannate complexes. Whereas in homo-ligand stannates (Table 8) the lengths of the Sn–X bonds are generally nearly equal, in the oxy-chloro stannate 30c, for example, the Sn–O bond is 5% shorter than in the dioxy compound 8 and the Sn–Cl bond is ca 4% longer than in triphenyltin complexes 32b–d. Thus, the tin atom is located 0.10 Å out of the plane formed by the three carbon atoms ($\Delta Sn$) in the direction of the aryloxy oxygen. Hence, the aryloxy anion is a strong donor with respect to the tin as compared with chloride ion. Analogously, the latter is a weak donor in comparison with cyanide ion ($\Delta Sn$ 0.07 Å). These X-ray data are in agreement with the solution behavior of the mixed-ligand complexes 36–38, where chloride ion (but not phenoxy ion) is split of preferentially, as well as with the fact that chlorine in Me$_3$SnCl can be displaced by the aryloxy group to form Me$_3$SnOAr but the oxygen ligand in Me$_3$SnOAr is not displaced by chloride under these conditions.
The difference in Sn–X bond distances in some homo-ligand complexes, in particular 42a,b and [Me₃SnCl₂][TMPH] (51), which are also included in Table 10, reflects the influence of hydrogen bonding between one of the ligands and a cation. In these cases, a hydrogen-bonded ligand acts as a weaker donor, and the tin atom is displaced from the equatorial plane to the direction of the ligand without hydrogen bond 229. In this connection, of particular interest is the stannate 51, in which the anion is distorted halfway between idealized four- and five-coordinate geometries (ΔSn 0.26 Å) 223.

The variation in the parameter ΔSn and the mutual changes in the axial bond lengths discussed above can be referred to in connection with a model for the S_N 2 reaction coordinate for substitution at tin. Following a Burgi–Dunitz-type analysis of crystal structures 261–263 for chloro stannate complexes, in which only the second axial ligand is changed, a series of the hydrogen-bonded stannates represents an early step in the reaction (Scheme 2). The case of X = Cl represents a symmetrical, near-TBP midway state for the reaction. For the oxy-chloro and cyano-chloro stannates the progress of the reaction is more advanced: the corresponding nucleophiles have essentially displaced the chlorine, which remains weakly coordinated, with the pyramidal inversion of the tin center.

SCHEME 2. Simulated S_N 2 reaction coordinate: the variation of ΔSn as a function of X in chloro stannates

A qualitative MO description of the homo- and mixed-stannate anions in terms of frontier orbitals supported by the structures of the known stannates is given by Suzuki and coworkers 226. According to the hypervalency theory 19,22,264–266, pentacoordinate triorganostannates bearing two electronegative substituents have a hypervalent nature. The central tin atom has three sp² orbitals forming the equatorial bonds and a p orbital. The latter is available for creating the apical bonds with three-center, four-electron configurations and, because the HOMO is derived from a nonbonding MO, the electronegative groups are utilized to form such bonds. This approach is particularly compatible with the observation of a pronounced effect of the two axial ligands on each other and the overall stability of the hypervalent complexes.

c. NMR spectroscopy. NMR data reveal the hypervalent nature of the homo- and mixed triorganostannates with TBP structures 219,266,267. The 119Sn chemical shifts and the one-bond carbon–tin coupling constants, 1^J(119Sn−13C), are summarized in Table 11. Changes in the coordination number at tin have a dramatic effect on the shielding and a wide range of 119Sn values are observed from the relatively deshielded Me₃SnCl (δ¹¹⁹Sn = 154.3 ppm, c-C₆H₁₂ 271), Ph₃SnCl (δ¹¹⁹Sn = −48 ppm, CDCl₃ 272) or (n-Bu)₃SnOPh (δ¹¹⁹Sn = 105 ppm, pure 273) to the more shielded anionic species.

The NMR data (δ¹¹⁹Sn and 1^J(¹¹⁹Sn−¹³C)) for stannates 30, 33, 36, 39, 40 219,226 suggest that exchange phenomena occur in solution according to equations 4 and 5. The value of δ¹¹⁹Sn for these equilibria depends on the nature of the equatorial organic groups and the apical heteroatom substituents, the cation M⁺ and the temperature. The influence of hydrogen bonding in solution is reflected in a markedly downfield shift

$^{c}$At $-80^\circ$C.

$^{d}$$\delta^{19}$F$_{Fbr}$($^{1}J^{(119}$Sn−$^{19}$F)$_{Fbr}$).

$^{e}$At $-70^\circ$C.

$^{f}$Average value.

$^{g}$$J^{(119}$Sn−$^{13}$C).

$\delta^{119}$Sn = 153.7 ppm for 51$^{223}$ as compared to the other general pentacoordinate stannanes (Table 11). The tin chemical shifts for 51 are strongly temperature-dependent. At the low-temperature limit the structure of the tin anion could be described as distorted halfway between idealized four- and five-coordinate geometries (Scheme 2).

Solid state CP/MAS $^{119}$Sn NMR spectra are fully in accord with these changes in the anions. The $^{119}$Sn resonance shifts upfield in the solid state versus that in solution by ca
50 ppm, e.g. from $-6.5$ to $-50$ ppm for $[\text{ClSn}((\text{CH}_2)_6)_3\text{SnCl} \cdot \text{F}] [n\text{-Bu}_4\text{N}]$ ($52a$) and from $-149.0$ to $-204.4$ ppm for $[\text{Me}_3\text{SnCl}((\text{CN})][\text{Et}_4\text{N}]$ ($39a$).

$^{19}$F and $^{119}$Sn variable-temperature NMR studies of $[\text{Bu}_3\text{Sn}_2][\text{Bu}_4\text{N}]$ show the presence of two distinct tributyltin species in equilibrium, the $\text{trans-Bu}_3\text{SnF}_2^{-}$ and $\text{trans-}([\text{Bu}_3\text{SnF}_2]_2\text{F}^{-}$ anions.

As shown by $^{19}$F and $^{119}$Sn NMR spectroscopies, fluorine exchange in the $\text{Ph}_3\text{SnX} - \text{Ph}_3\text{SnFX}^{-}$ system ($X = \text{F, Cl}$) occurs between four- and five-coordinated tin complexes, presumably via fluorine- and chlorine-bridged intermediates, while phenyl–tin bonds were not cleaved during any of the ligand-exchange processes. The proposed mechanism (equation 6), including bridged intermediates of the type $53$, is in agreement with the fact that purified $\text{Ph}_3\text{SnF}_2^{-}$, containing no $\text{Ph}_3\text{SnF}$, does not undergo fluorine exchange. This result eliminates simple ionization of $\text{Ph}_3\text{SnF}_2^{-}$ and the loss of $\text{F}^{-}$ as a mechanism for the fluorine exchange.

\[
\begin{align*}
\text{Ph} & \quad \text{Sn} \quad X + \quad \left[ \begin{array}{c}
\text{Ph} \\
\text{Sn} \\
\text{X} \\
\text{Ph}
\end{array} \right] \\
\text{Ph} & \quad \text{Sn} \quad \text{F} \quad \text{Ph} \\
\text{X} & \quad \text{Sn} \quad \text{Ph} \quad \text{Ph}
\end{align*}
\]

$X = \text{F, Cl}$

In connection with equation 6, the fact that the five-coordinated 1 : 1 adducts $\text{Ph}_3\text{SnF} \cdot \text{HMPA}$, $\text{Ph}_3\text{SnF} \cdot \text{DMSO}$ and $\text{Ph}_3\text{SnFCl}^{-}$ undergo rapid fluorine exchange and disappearance of $\text{Sn} - \text{F}$ coupling suggests that partial dissociation of adducts to give the four-coordinated tin species is taking place. Moreover, an addition of a large excess of HMPA, DMSO or $\text{Cl}^{-}$ to the corresponding adducts stops the fluorine exchange in these adducts owing to a decrease in the concentration of the four-coordinated species by the action of the excess Lewis base.

The results are relevant to the mechanism of the isomerization and racemization of triorganotin halides, which may include the selective cleavage of the bridging halogen bonds in unsymmetrical intermediates $\text{X} - \text{SnR}_3 - \text{Y} - \text{SnR}_3 - \text{D}$ ($\text{D} = \text{donor}$) like $53$.

### 3. Bridged triorganostannates

Recently, the complexation ability of organotin compounds containing two or more tin atoms bridged through carbon as multifunctional Lewis acids toward halide ion in host–guest chemistry were investigated intensively. Commonly, the reaction of bis(halodiphenylstannyl)alkanes ($\text{Ph}_2\text{XSn}((\text{CH}_2)_n)(\text{CH}_2)_n(X = \text{F, Cl, Br, I}; n = 1 - 3)$ and halide ions $Y^{-}$ ($Y = \text{F, Cl, Br}$) as the corresponding ammonium salts in dichloromethane solution led to anionic 1 : 1 adducts $[\text{Ph}_2\text{XSn}((\text{CH}_2)_n) \cdot Y]^{-}$ ($52b$, $n = 1, X = Y$); $52c$, $n = 1, X \neq Y (Y = \text{F})$; $52d$, $n = 2$; $52e$, $n = 3$) containing bridged halogen and two pentacoordinated tin atoms. $\text{Me}_2\text{ClSn}((\text{CMe}_2)_2 \cdot \text{F}^{-}$ ($52f$) was prepared in a similar way. The bis(halodiphenylstannyl)alkanes always preferentially chelate fluoride ion over chloride or bromide, and in the case of $X \neq Y$ ($Y = \text{F}$), fluoride ion is bridged in the final adducts. Methylene-bridged 1 : 1 adducts $52b$ ($X = \text{Y} = \text{F, Cl, Br}$) and $52e$ ($X = \text{Cl, Br}; Y = \text{F}$) eventually react with the additional fluoride ion (but not chloride or bromide ion) to give the 1 : 2 tetrafluoro adduct $[\text{Ph}_2\text{F}_2\text{Sn}((\text{CMe}_2)_2]^{-}$ ($52g$) (Scheme 3). Ethylene-bridged 1 : 1 adducts $52d$ ($X = \text{Y}$) appear to be particularly stable and do not react with halide ions (only the bridged chlorine is exchanged by fluorine). In contrast, for propylene-bridged adducts $52e$ ($X = \text{Y} = \text{F, Cl}$) the exchange occurs as well as an
SCHEME 3. Principal reaction scheme for the formation of methylene-bridged adducts
interaction with both fluoride and chloride ion resulting in the formation of 1 : 2 adducts 52h. All the 1 : 2 adducts include two pentacoordinate tin atoms.

![Diagram](image)

The principal products of the reaction between bis(halodiphenylstannyl)alkanes and halide ions as well as some intermediate species were identified by \(^{119}\text{Sn}\) and \(^{19}\text{F}\) spectroscopies. The ammonium salts \([^\text{[(Ph}_{2}\text{XSn)}_{2}\text{CH}_2\cdot F\text{][Et}_4\text{N}] (52b, X = F; 52c, X = Cl, Br, I, [\text{[(Ph}_{2}\text{XSnCH}_2)]_{2}\cdot F\text{][Et}_4\text{N}] (52d, X = F, Cl) as well as [\text{[(Me}_{2}\text{ClSn)}_{2}\text{CMe}_2\cdot F\text{][Et}_4\text{N}] (52f) were isolated. The salt \([^\text{[(Ph}_{2}\text{ClSnCH}_2)]_{2}\cdot Cl\text{][}\text{(Ph}_3\text{P)}_{2}\text{N}] (52d, X = Y = Cl) was also isolated.\text{^269}]

More recently, \(o\)-bis(haloorganostannyl)benzenes were found to be powerful bidentate Lewis acids toward halide ions\textsuperscript{215}. Treatment of \(o\)-C\(_6\)H\(_4\)(SnMe\(_2\)X)\(_2\), \(X = \text{Cl, F} (52i\text{ and } 52j)\) with 1 molar equivalent of the halide ion afforded the corresponding anionic 1 : 1 complexes 52k, \(X = Y = \text{F, M = Et}_4\text{N, K \cdot 18-crown-6; X = Y = Cl, M = (Ph}_3\text{P)}_{2}\text{N; X = Cl, Y = F, M = Et}_4\text{, K \cdot dibenzo-18-crown-6} (\text{equation 7).}

![Diagram](image)

No dianionic 1 : 2 adducts were observed even with excess of halide ions. As in the case of the bis(chlorodiphenylstannyl)alkanes\textsuperscript{238}, the affinity of 52i to fluoride is greater than that toward chloride. This suggests, in particular, \textit{in situ} formation of the fluoride complexes \([o\text{-C}_6\text{H}_4(\text{SnMe}_2\text{Cl})\cdot F][\text{M}] (M = (\text{Ph}_3\text{P)}_{2}\text{N, Bu}_4\text{N}) by the reaction of the chloride complex 52k, X = Y = Cl, M = (Ph\(_3\text{P)}_{2}\text{N with KF in CH}_2\text{Cl}_2 as well as by the reaction of 52i with [Ph\(_3\text{SnF}_2]^-\text{[Bu}_4\text{N]}^+ (47) in the same solvent.
These results are in agreement with the data\textsuperscript{213} that the anion in the complex \{ClSn[(CH\textsubscript{2})\textsubscript{8}SnCl\textsubscript{2}][Ph\textsubscript{3}PCH\textsubscript{2}P\textsubscript{3}] (52i)\} is a stannate-stannane species wherein one of the Lewis acidic tin atoms binds the chloride strongly, and the other interacts weakly with the chloride. At the same time, the anion in the complex \{ClSn[(CH\textsubscript{2})\textsubscript{6}SnCl·F][Bu\textsubscript{4}N] (52a)\} is a bis-hemistannate species wherein one of the Lewis acidic tin atoms binds simultaneously the guest fluoride.

Information on the related complexation ability of organotin chlorides was provided by the \textsuperscript{119}Sn NMR investigations of equimolar amounts mixtures of [Ph\textsubscript{3}P=N=NPh\textsubscript{3}]\textsuperscript{+}Cl\textsuperscript{−} and two or three corresponding organotin compounds\textsuperscript{215}. The following qualitative sequence for the affinity of organotin chlorides as hosts toward chloride ions was obtained: Ph\textsubscript{3}SnCl ≪ Ph\textsubscript{2}SnCl\textsubscript{2} ≪ (Ph\textsubscript{2}ClSnCH\textsubscript{2})\textsubscript{2} ≈ (Ph\textsubscript{2}ClSn)\textsubscript{2}CH\textsubscript{2} ≈ o-C\textsubscript{6}H\textsubscript{4}(SnMe\textsubscript{2}Cl)\textsubscript{2} (52i) ≪ (PhCl\textsubscript{2}Sn)\textsubscript{2}CH\textsubscript{2} ≈ o-C\textsubscript{6}H\textsubscript{4}(SnMeCl\textsubscript{2})\textsubscript{2}. The sequence shows that the bidentate ditin species are more efficient in comparison with the monotin derivatives and that the stability of the adducts formed is apparently affected not only by the Lewis acidity of the two tin centers but is also assisted by formation of particularly stable five-membered chelate rings.

Another case of bridging reported recently is in the series of anionic adducts 54–56 with methylene-bridged tri- and tetra-tin framework\textsuperscript{214}.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure.png}
\caption{Chemical structures of the anionic adducts 54–56.}
\end{figure}

They were synthesized by the reaction of halides with the corresponding tri- or tetranuclear tin compounds, (XPh\textsubscript{2}SnCH\textsubscript{2})\textsubscript{2}SnPX and (XPh\textsubscript{2}SnCH\textsubscript{2}SnPhX)\textsubscript{2}CH\textsubscript{2} (X = F, Cl). The structure of 54c was proved by X-ray crystallography, and variable-temperature \textsuperscript{119}Sn and \textsuperscript{19}F NMR studies indicate that the structure observed for the anion in 54c in the solid state is retained in solution. Analogously, NMR spectral data suggest the structure of the trinuclear adducts 54a, 54b, 55 and the tetranuclear tin chloride complex 56. In contrast, \textsuperscript{119}Sn and \textsuperscript{19}F NMR data show that the tetranuclear tin fluoride reacts with fluoride ion to give a stable 1 : 2 adduct 57. Its structure in solution was postulated\textsuperscript{214} on the basis that more electronegative fluorine atoms would occupy axial positions in TBP geometries at five-coordinate tin atoms.

\(^a\)For two tin atoms.
\(^b\)Bridged halogen.
\(^c\)Terminal halogen atom.
\(^d\)Toward the terminal halogen atom.
\(^e\)Toward the bridged halogen atom.
\(^f\)For the terminal tin atom.
\(^g\)For the internal tin atom.

Some of the crystallographic data for anions in bridged di- and tri-tin complexes \(52\) \(52b\), \(52c\), \(52d\), \(52f\), \(52k\), \(52l\) and \(54\) are collected in Table 12. With the possible exception of the anion \{ClSn[(CH\(_2\)_8]_3SnCl\(_2\)\}\(^−\) in salt \(52\) \(213\), all anions have distorted TBP geometries around the tin atoms with the equatorial plane being defined by the carbon atoms in each case. The Sn−Hal\(_{br}\) and Sn(2)−Hal\(_{br}\) (br = bridge) distances are generally not equal, resulting in the formation of a skewed rombus for the anions with a central four-membered ring. Each of the Sn atoms in ditin complexes lies out of the trigonal plane defined by the three carbon atoms.
in the directions of the terminal halogen atom. Thus, the latter is a stronger donor atom as compared with a bridged halogen. The structures of the anions discussed represent an early step in the SN2 reaction coordinate for substitution of a halogen at tin by added halide ion (Scheme 2).

The availability of several closely related structures enables systematic comparison of their derived interatomic parameters. In the case of the anions 52b, X = F, 52c, X = Br, I and 52f comprising a central four-membered ring, the distortion of the axial Fbr–Sn–Hal angles increases in the sequence F ⩽ Cl < Br < I. The average differences between the Sn–Hal(terminal) bond length and the ‘standard’ value determined for tetrahedral derivatives follow the sequence F ≪ Br ≈ I < Cl. Consequently, in the case of terminal F atoms, the Sn–Fbr(terminal) distance is the shortest in accordance with the high affinity of fluoride to tin as compared to the other halides. Moreover, in the anion of the complex 52d, X = Cl, Y = F with less strained central five-membered ring, the Sn–Fbr distance is shorter than that in the anions containing four-membered rings, and the fluorine bridge is symmetrical.

In contrast to the anion of the complex 52d, X = Cl2, in the analogous trichloride anions of complexes 52k, X = Y = Cl, M = (Ph3P)2N215 and 52d (X = Y = Cl)269 the Sn(1)ClSn(2) bridge is slightly asymmetric. Consequently, the Sn(1)–Clbr and Sn(2)–Clbr distances are not equal (Table 12). In comparison with the latter compounds, the anion of the complex 52k, X = Cl, Y = F, M = K · dibenzo-18-crown-6215 shows a greater asymmetry due to the interaction between K+ and one of the terminal chlorine atoms.

A peculiarity of the anion structure in the tritin complex 54c214 is that the central tin atom does not deviate from the equatorial plane defined by the carbon atoms. The Sn(central)–Fbr–Sn(terminal) fragment is more asymmetrical than in the related bridged fragment in 52b, X = F.

Solid state CP/MAS 119Sn NMR spectra are in good agreement with the molecular structures of bridged stannates discussed above. In particular, the spectrum of the F-bridged complex 52a comprises a doublet centered at δ = −50 ppm and F coupling constant of 1120 Hz, while for the stannane-stannate complex 52l, the upfield signal is assigned to the stannate tin (−24 ppm) and the downfield signal (+128 ppm) to the stannane tin213. Variable-temperature 119Sn and 19F NMR spectra of the trifluorides [(Ph2FSn)2(CH2)n · F]−Bu4N+ (n = 1–3) indicate an intramolecular exchange of the terminal and chelate fluorine atoms resulting from rupture of Sn–F (bridged bond) and rotation about a Sn–C bond in the methylene bridge (as shown for n = 1 in equation 8)238.

\[
\begin{align*}
\text{Ph} & \qquad \text{Sn} & \qquad \text{Sn} & \qquad \text{Ph} \\
\text{F} & \quad \text{F} & \quad \text{F} & \quad \text{F} \\
\text{Ph} & \quad \text{Ph} & \quad \text{Ph} & \quad \text{Ph}
\end{align*}
\]

The energy barrier for the endocyclic Sn–C bond rotation is higher for the trifluoride with n = 2 than for the anion with n = 1, indicating that the five-membered SnFSnCC ring is more stable than the four-membered SnFSnC ring. These results correlate well with earlier data on exchange processes in complexes 52l and 52a, for which the activation energies are 5.3 and 2.9 kcal mol−1, respectively213.

4. Diorganostannates

The interaction of diorganotin dihalides with halide ions (usually as the ammonium or potassium salts) can lead to the formation (equation 9; either X = Y or Y ≠ X) of
either trihalodiorganostannate or tetrahalodiorganostannate salts. The structure of the complexes isolated depends on the ratio of reagents, the nature of the halide, the cation, the ligands at tin and the solvent.

\[
\begin{align*}
R_2SnX_2 + Y^- & \rightarrow R_2SnX_2Y^- \quad (58a) \ R = Me \\
R_2SnX_2 + 2Y^- & \rightarrow R_2SnX_2Y_2^{2-} \quad (59a) \ R = Me
\end{align*}
\]

The trend for the formation of the monoanions increases from the lighter halogens to the heavier halogens. Thus, the reaction of an aqueous solution of Me_2SnF_2 with NH_4F in a 1 : 2 molar ratio gives both [Me_2SnF_3][NH_4] and [Me_2SnF_4][NH_4]^2, while the same reaction in a 1 : 3 molar ratio yields only the latter. However, the reaction between Me_2SnBr_2 and Alk_4NBr yielding the monoanionic complexes [Me_2SnBr_3][Alk_4N] (58a, Alk = Me, Et) is independent of molar ratio in water (58a, Alk = Et; 1 : 1 or 1 : 2 molar ratio of reagents) and in ethanol (58a, Alk = Et; 1 : 1). The reaction of Me_2SnBr_2 with Et_4NBr in CHCl_3/hexane mixture, in 1 : 2 molar ratio, unlike the above reaction in water, gives dianionic complex [Me_2SnBr_4][Et_4N]^2 (59a), which is independent of molar ratio in water (58a, Alk = Et) and therefore low solvation enthalpies would favour the formation of 59a. Consequently, when the reaction is performed in a highly solvating solvent such as water, pentacoordinate complex 58a, Alk = Et crystallizes. However, in solvents with a lower solvating capacity like the CHCl_3/hexane mixture, hexacoordinate complex 59a is formed.

Earlier attempts to isolate the anionic iodide complexes Me_2SnI_3^- and Me_2SnI_4^- had failed. Moreover, it was recently shown that the previously reported [Me_2SnI_4][Bu_4N]^2 is actually a 1 : 1 mixture of [Bu_4N] and [Me_2SnI_3][Bu_4N]. The pure salts [R_2SnI_3][Bu_4N] (R = Me, Ph) were obtained by a stoichiometric reaction of R_2SnI_2 with Bu_4NI in CH_2Cl_2 in the absence of light. A TBP arrangement for the R_2SnI_3^- anions was proved by IR, Raman and ^119Sn Mössbauer spectroscopies and by X-ray powder diffraction data.

Like stannates R_2SnX_2^- discussed above, diorganotrihalostannates R_2SnX_3^- can be obtained by the interaction of the corresponding organotin halides with neutral donors. Hence the reaction of Ph_2SnCl_2 with 8-methoxyquinoline (L) in cyclohexane gives the pentacoordinate [Ph_2SnCl_3][LH] (60) and the hexacoordinate tin complex [Ph_2SnCl_4][LH]^2 (61) as well as dimeric distannoxane [Ph_2SnCl_2]_2O_2. The latter is a product of a partial hydrolysis of Ph_2SnCl_2 due to the presence of water in the solvent. The anion Ph_2SnCl_3^- of 60 disproportionated into Ph_2SnCl_2 and [Ph_2SnCl_4]^2 upon heating in chloroform. Consequently, the formation of the latter is due to the disproportionation reaction (equation 10) rather than to addition of chloride ion to Ph_2SnCl_3^-.

\[
2Ph_2SnCl_3^- \rightleftharpoons Ph_2SnCl_2 + Ph_2SnCl_4^{2-} \quad (10)
\]

The formation of pentacoordinated stannates 62a and 62b has been detected in the hydrolysis of the organotin halide complexes with phosphoryl ligands containing aliphatic amino group in the ligand. The tentative reaction scheme is shown in equation 11.

The first tin hydride complex [Bu_2SnI_2H][Li] was recently synthesized. The observed upfield ^119Sn chemical shift (~177.9 ppm in THF-d_8) and spin–spin coupling constants [^1J(^119Sn^–^13C) 498 Hz, ^1J(^119Sn^–^1H) 2318 Hz] as compared with those for Bu_2SnIH (~76.3 ppm, 408 and 2060 Hz, respectively) strongly indicate the formation of a pentacoordinated tin complex.
The X-ray crystallographic structures of a number of diorganotrihalostannate complexes were briefly analyzed. A significant structural diversity of the anions was found. The fluoro-anion in the complex [Me₄Sn₂F₅][Et₄N] displays linear, fluoride-bridged units resulting in a six-coordinate tin. The dinegatively charged chloro-anion Me₆Sn₃Cl₈²⁻, which can be considered as the adduct Me₂SnCl₂ · 2Me₂SnCl₃⁻, includes three hexacoordinated tin atoms, as well as distorted TBP with an additional Cl → Sn contact near the equatorial plane of the bipyramid in dimers, having coordination environment of two tin atoms that can be classified as a distorted octahedron. Principal geometric parameters of these anions are given in Table 13.

Bond distances between tin atom and the two axial chlorine atoms in the isolated TBP anions 63 are significantly longer (2.52–2.62 Å) than the equatorial Sn–Cl bond (2.32–2.40 Å).

In accordance with the theory of hypervalent bonds, the CSnC angle constricts and the lengths of equatorial and terminal axial bonds Sn–Cl diverge with the reduction of the secondary Cl → Sn interaction. An interesting feature of some structures [see entries 6, 8, and 8 (62a) in Table 13] is that the axial Sn–Cl bond not involved in the secondary Cl → Sn interaction is longer than the other axial bond, probably due to specific interactions between the terminal chlorine atom and cation (hydrogen bonds in entries 6 and 8 and Cl···S contacts in entry 7). It is still unclear why some diorganotrichlorostannates exist as dimeric anions while others do not. Nevertheless, it is noteworthy that there are no examples of hydrogen-bonded anion-cation pairs among the structures containing isolated anions and all phenyltin derivatives (entries 11–13) form isolated anions. As for alkyl derivatives, the diversity of tin coordination polyhedra suggests that both edge-sharing octahedron and isolated TBP possess similar energies, hence relatively weak crystal packing forces control the choice between these forms.

An X-ray crystallographic study of 58a, Alk = Me (entry 14) revealed the first example of a TBP structure containing an R₂SnBr₃⁻ anion. In contrast to the structures observed for Me₂SnCl₃⁻ anions that are generally associated as dimers, the Me₂SnBr₃⁻ anion is...

TABLE 13. Comparison of the principal geometric parameters for isolated R₂SnX₃⁻ and dimeric [R₄Sn₂X₆]²⁻ anions.
monomeric. The TBP structure of the Me$_2$SnBr$_3$\(^-\) anion in complex 58b was proved by IR, Raman and $^{119}$Sn Mössbauer and MAS NMR spectrosocopies in the solid state, and by $^{119}$Sn NMR spectroscopy in solution (Table 11)\(^{270}\).

The dinegatively charged anion 65 obtained as its 2-aminopyrimidinium salt, by the reaction of Ph$_2$SnCl$_2$ and 2-aminopyrimidine in the presence of diethyl ether, followed by recrystallization from a MeCN/MeOH mixture is the first example of a five-coordinated anionic distannoxane\(^{299}\). Its X-ray crystal structure resembles the dimeric anions 64 and consists of tin units with di-$\mu$-oxo bridging. The coordination geometry of the tin unit is a distorted TBP with two phenyl groups and one $\mu$-oxo, at a Sn-O distance of 2.032 Å, in equatorial positions, and the other two $\mu$-oxo and chlorine atoms, at a O $\rightarrow$ Sn distance of 2.187 Å and Sn-Cl = 2.467 Å, in axial positions. The ranges of Sn-O bond lengths, and of the OSnO and SnOSn bond angles, are close for all the distannoxanes\(^{299}\).

Anionic sulfur as well as chloride bridged ditin complexes 66a–c were most recently prepared by the reaction of diorganotin sulfides, cyclo-(R$_2$SnS)$_n$ ($n = 2, 3$) with the appropriate amounts of R$_2$SnCl$_2$ in the presence of [(Ph$_3$P)$_2$N]Cl\(^{300}\). Single-crystal diffraction studies of 66a,c revealed the first crystallographic examples of structures containing a Sn($\mu$-S)($\mu$-Cl)Sn core. The geometry about each tin atom is best described as TBP with the equatorial and axial positions being occupied by two C and one S, and by two Cl, respectively, in each case. The respective ClSnCl axial angles are 175.1° and 173.6° for 66a but 166.6° and 165.6° for 66c. As expected, the Sn-Cl(bridging) distances (2.74–2.83 Å) are significantly longer than the Sn-Cl(terminal) distance (2.47–2.51 Å). Both tin atoms are displaced out of the C$_2$Sn equatorial plane in the direction of the Cl(terminal) atoms, by 0.12 and 0.16 Å for 66a.

The $^{119}$Sn, $^{13}$C and $^1$H NMR spectra in CDCl$_3$ are in agreement with the exclusive formation of 66a,b in solution, while the equilibrium \{[Sn(t-Bu)$_2$SnCl]$_2$·Cl$^-\} \rightleftharpoons 1/2[[t-(Bu)$_2$SnS]$_2$ + (t-Bu)$_2$SnCl$_3$\(^-\) takes place for the anion in 66c\(^{300}\).

A number of hypervalent tin species including the monoanions [Ph$_2$SnCl$_2$F]$^-$, [Ph$_2$SnClF$_2$]$^-\) and [Ph$_3$SnF$_3$]$^-$, as well as the dinegatively charged anions [Ph$_2$SnF$_4$]$^{2-}$ and [Ph$_2$SnCl$_4$]$^{2-}$, have been identified in CH$_2$Cl$_2$ solutions of Ph$_2$SnCl$_2$ and Bu$_4$NF·3H$_2$O mixtures by $^{119}$Sn and $^{19}$F NMR spectroscopy\(^{237}\). The NMR data are consistent with static TBP geometries at $-100$ °C for both [Ph$_2$SnCl$_2$F]$^-$ and [Ph$_2$SnClF$_2$]$^-$, while at $-60$ °C the latter become fluxional, probable via a Berry pseudorotation mechanism. Variable-temperature $^{119}$Sn and $^{19}$F NMR spectra of the Ph$_2$SnF$_3$\(^-\) anion are indicative of intramolecular exchange of axial and equatorial fluorine atoms followed by an intermolecular fluoride exchange at a higher temperature. It was also found that the addition of fluoride ion to Ph$_2$SnCl$_2$ causes appreciable migration of the Ph group to give the [Ph$_3$SnClF]$^-$ and [Ph$_3$SnCl$_2$]$^-\) anions as minor species. In chloride or bromide
ion addition to diorganotin dihalides, only the 1:1 adducts R₂SnX₃⁻ (R = Me, Bu, Ph; X = Cl, Br) have been detected.

High level ab initio SCF MO calculations of monoanions Me₂SnX₃⁻, their precursors Me₂SnX₂, the dinegatively charged anions trans-Me₂SnX₄²⁻ (X = F, Cl, Br, I) as well as the related derivatives cis-R₂SnCl₄²⁻ (R = Me, Et), Et₂SnCl₂, Et₂SnCl₃⁻ and trans-Et₂SnCl₄²⁻ have been recently reported. The gas-phase formation of pentacoordinate R₂SnX₃⁻ anions from R₂SnX₂ and X⁻ is an exothermic process, while the following addition of X⁻ to monoanions R₂SnX₃⁻ is an endothermic one. The pentacoordinate R₂SnX₃⁻ anions show a TBP geometry with the R groups in equatorial positions and longer Sn−X distances for the axial bonds than for the equatorial ones. Thus, these calculations are in good agreement with experimental data.

5. Organotetrahalostannates and related species

As compared to anions of the R₃SnHal₂⁻ or R₂SnHal₃⁻ types, much less is known about the nature of halide adducts of monoorganylhalostannanes. In particular, the tin atom in the salt [MeSnCl₄][Ph₄As] has approximately a TBP coordination, with the carbon atom occupying an equatorial position. The equatorial Sn−Cl distances are ca. 2.34 Å while the axial distances are longer at ca. 2.45 Å (Table 13, entry 15).

A number of hypervalent tin species, including MeSnCl₄⁻, BuSnCl₄⁻, PhSnCl₄⁻ and PhSnCl₂F²⁻, are identified in the reactions of chloride ion or fluoride ion with monoorganyltin halides RSnCl₃ (R = Me, Bu, Ph) in CH₂Cl₂ solution using variable-temperature ¹⁹F and ¹¹⁹Sn NMR spectroscopies. The Ph group migration with formation of the five-coordinated anion, PhSnCl₄⁻, has been observed to be reversible (equation 12).

\[
\text{Ph}_2\text{SnCl}_2 + [\text{SnCl}_6]^{2-} \rightleftharpoons 2[\text{PhSnCl}_4]^- \tag{12}
\]

Unlike the interaction of bis(halodiphenylstannyl)alkanes with halide ions which lead to anionic 1:1 adducts with bridged halogen, ¹¹⁹Sn NMR spectroscopy indicates the formation of five-coordinate dinuclear 1:2 chloride and bromide complexes 67a−d, and 68a,b, respectively, from the reactions between X₃Sn(CH₂)ₙSnX₃ (X = Cl, Br; n = 1, 3, 4, 8) and halide ions in CHCl₃ solution (equation 13).

\[
\text{Cl}_3\text{Sn(CH}_2)_n\text{SnCl}_3 + 2\text{MX} \rightarrow \text{[MX]}^{2-} \tag{13}
\]

MX = [BnPPh₃]Cl, R₄NBr
The crystal structure of 67c reveals a distorted TBP geometry about each tin atom with the two axial Sn−Cl bond distances being significantly longer than the equatorial Sn−Cl bonds (Table 13, entry 16). Moreover, a significant disparity is noted between the axial Sn−Cl distances (0.08 Å) that is explained in terms of Cl···H interactions. As a result, the tin atom lies 0.08 Å out of the equatorial CCl₂ plane in the direction of the chlorine atom having the shorter bond length.

The allylation reaction of CH₂O by the pentacoordinate adducts F₄M(CH₂CH=CH₂)⁻ (M = Ge, Sn) was studied by the ab initio Hartree–Fock method. Their adduct formation from F₃M(CH₂CH=CH₂) and F⁻ is exothermic. These adducts display enhanced nucleophilicity of the allylic γ-carbon and a significant Lewis acidity and form hexacoordinate adducts F₄M(OCH₂)(CH₂CH=CH₂)⁻ by the addition of CH₂O. The reactivity of the Ge and Sn complexes is expected to be greater than that of their Si analogues because of the lowering of the potential energy barriers.

Anionic complexes [PhPbX₄][Ph₄E] (X = Cl, Br; E = P, As) have been prepared by the reaction of PhPb(O)OH with HCl or HBr and Ph₄EX₃. Anionic complexes of the simplest pentacoordinate germanane species, GeCl₅⁻, as the (1,2-bis(t-butylamido)ethene)-phosphenium and -arsenium salts has been described in both cases, the GeCl₅⁻ anion, like the SnCl₅⁻ anion (entries 19 and 20 in Table 13), has a near-regular TBP with the axial ClGeCl angles at ca 178° and the axial Ge−Cl distances at 2.25–2.32 Å while the equatorial bonds are shorter, being 2.12–2.17 Å, as expected.

6. Zwitterionic stannates

A number of zwitterionic stannates, namely 69a, 69b, 69c, 69d and Bu₃Sn(Cl)OCOCH₂CH₂PPh₃ (69e) were described, in which the tin is formally negative, with a cationic nitrogen or phosphorus as a part of the ligand. The carboxylato compounds were prepared in good yields by mixing ethanolic solutions containing stoichiometric quantities of Ph₃SnCl, Ph₃SnNCS or (PhCH₂)₃SnCl and 2-pyridinecarboxylic acid or 3-triphenylphosphonopropiobetaine, respectively. The geometry at tin is TBP, like in anionic and neutral pentacoordinate tin complexes. The Sn−O, Sn−Cl and Sn−N distances in these zwitterionic stannates are comparable to those for anionic stannates (Table 10).

The fluorostannyl-substituted phosphonium salts, (t-Bu)₂Sn(CH₂PPh₃)F₂ · BF₃ (69f) and (t-Bu)₂Sn[C(=CH₂)PPh₃]F₂ · BF₃ (69g), have an intermolecular contact between one fluorine atom of the BF₄ tetrahedron and the tin atom that leads to distorted TBP configurations of the tin atoms. Thus, these complexes can be considered as zwitterionic stannates with the formally negatively charged tin atoms including one normal Sn−F distance while the other Sn···F contact is elongated by 0.755 Å in 69f and 0.88 Å in 69g (Table 10). The tin atom is displaced out of the plane formed by the three carbon atoms at 0.35 Å in 69f and 0.32 Å in 69g, respectively. The relative shortening of the averaged Sn−F bonds (ca 2.41 Å) is ca 23% as compared to those of the corresponding tetrahedral derivatives. This shortening is larger than that in the corresponding dichloro- and dibromo-triorganylstannates (see above).

B. Intramolecular Complexes

Various monocyclic and bicyclic pentacoordinate anionic germanium and tin complexes are known which possess bidentate dianionic oxo and related ligands, such as aliphatic or aromatic 1,2-diols, α-hydroxycarboxylic acids and their thio analogues (for early references see References 191, 307–309). Anionic mono- and bis-chelated germanium and
tin compounds containing four-membered ring were discussed in a review\textsuperscript{310} and are not reviewed here.

1. Monocyclic derivatives

   a. Tin. The monocyclic organostannates 69h and 69i with four Sn–C bonds were recently prepared by the reaction of their corresponding tetracoordinate precursors 69j and 69k with \( p \)-TolLi (equation 14)\textsuperscript{311}. The complexes obtained were found to be thermally stable but were unstable to moisture, giving quantitatively the initial compounds upon aqueous workup.
119Sn NMR spectra of the solution of 69j and 69k with p-TolLi show a remarkable upfield shift relative to those for 69j and 69k, $\Delta \delta = 182$ and 212 ppm, respectively, indicating an increase in the coordination number of tin. It is noteworthy that the organostannates 69h and 69i react with 1,3-bis(methoxycarbonyl)pyridinium chloride to give the corresponding alkylated(arylated) dihydropyridines.311

The triphenyltin derivatives of oxalic acid 70a, 70b, mercaptoacetic acid 71 and 2-mercaptobenzoic acid 72 were prepared by the reaction of triphenyltin hydroxide with the corresponding amine and acid in a 1 : 1 : 1 molar ratio.

X-ray crystallography of stannates 70–72 revealed rare examples of a cis-TBP geometry at tin with oxygen and one of phenyl groups in the apical positions. The axial Sn–O bonds are longer than those in tetrahedral derivatives and, of the three Sn–C bonds, the axial bond is statistically longer than the two equatorial bonds (Table 14).

Organotin 1,2-dithiolate complexes were featured in many studies; the ligands used include aliphatic derivatives, e.g. ethane-1,2-dithiolate $-SCH_2CH_2S^-$ (EDT), $-SCH_2CHMeS^-$, alkenyl derivatives, e.g. $-SCH=CHS^-$, maleonitriledithiolate (MNT), aryl derivatives, 1,2–$-SC_6H_4S^-$ (BDT) and toluene-3,4-dithiolate (TDT), as well as heterocyclic derivatives, 1,3-dithiane-2-one-4,5-dithiolate (DMIO) and 1,3-dithiane-2-thione-4,5-dithiolate (DMIT)191.

The general synthetic route to monocyclic complexes $[R_3M(MNT)] [Alk_4N]$ (M = Ge, Sn, Pb; R = Me, Ph) involves the reaction between Na2(MNT) and RMCl3 in the presence of tetraalkylammonium halides. In the case of Ph3SnCl and NH4Br, this reaction proceeds without tin–carbon bond cleavage giving the stannate [Ph3Sn(MNT)]$^-$ as its Me4N$^+$ salt 73316.

<sup>a</sup>Average value.
<sup>b</sup>C<sub>eq</sub>SnO<sub>eq</sub>.
<sup>c</sup>Two independent ion pairs.

An X-ray study shows that the anion in 73 can be referred to a TBP. However, the remarkable difference between the Sn–S<sub>eq</sub> bond length of 2.496 Å and the Sn–S<sub>ax</sub> bond length of 2.864 Å (Table 14), which significantly exceeds the typical range for Sn–S<sub>ax</sub> bond lengths (2.49–2.54 Å), is evident for a residual tetrahedral character at the tin atom. The latter is displaced 0.28 Å out of the equatorial plane in a direction away from S<sub>ax</sub>. Retention of the solid state structure of the anion 73 in solution is supported by the high negative value of −173.8 ppm (1:1, CDCl<sub>3</sub>/CH<sub>3</sub>CN) observed in the <sup>119</sup>Sn NMR spectrum.

Other examples of monocyclic dithiolato stannates are two series of diorganohalo– and diorganopseudohalo–tin complexes, containing DMIO and DMIT ligands, which were recently obtained from organotin halides and the dithiolato Zn derivatives (Scheme 4)<sup>191</sup>,<sup>309</sup>,<sup>318</sup>. When these reagents were used in a 2:1 ratio, the DMIO or DMIT stannates, 74<sup>191</sup>,<sup>319</sup> and 75<sup>309</sup>,<sup>318</sup>, respectively, were generally obtained in acetone or methanol solution (stage a). Neutral diorganotin DMIO and DMIT compounds, 76<sup>191</sup> and 77<sup>197</sup>, were isolated by the following treatment of the reaction mixture with water (stage b). The stannates 74 and 75 could also be formed from the neutral compounds 76 and 77, respectively, on reaction with onium halides MX (stage c). Hence, in the preparation of 74 and 75, the presence of water required to remove the inorganic salts was kept to a minimum.

Another route to 74 and 75 is halide (pseudohalide) exchange reaction between the chlorides 74 or 75 (X = halogen) and NaX′ or KX′ (X′ = Br, I, NCS, NCS<sub>e</sub>)<sup>191</sup>,<sup>309</sup> (stage d). Analogously, exchanges of [R<sub>2</sub>Sn(DMIT)Cl][M] with I<sup>−</sup><sup>318</sup> or NCS<sup>−</sup><sup>320</sup> took place while attempts to replace Cl<sup>−</sup> by [Et<sub>2</sub>NCS]<sup>−</sup> had failed<sup>318</sup>.
Scheme 4. Formation of monocyclic DMIT and DMIO derivatives

(74) E = O; M = Et₄N, FeCH₂NMe₃; R = Ph, Alk; X, X' = Cl, Br, I, NCS
(75) E = S; M = Alk₄N, 4-MeC₆H₄NMe (DMP; R = Ph, Alk; X, X' = Cl, Br, I, NCS, NCSe, N₃
(76) E = O; R = Me, Et, Bu, Ph
(77) E = S; R = Me, Et, Bu, octyl, Ph, o-MeOC₆H₄
The interactions between the neutral DMIT derivatives 77 and MX (e.g. Et₄NB₃, Bu₄NB₃, stage c) were studied directly in solution by ¹¹⁹Sn NMR spectroscopy. The δ¹¹⁹Sn values recorded for the MX-R₂Sn(DMIT) systems reflect the average values for rapidly equilibrating R₂Sn(DMIT) and [R₂Sn(DMIT)]⁻ species.

X-ray diffraction shows that the DMIO and DMIT complexes, 74a-c (74a, M = Et₄N, R = Ph, X = Cl); 74b, M = Et₄N, R = Et, X = Br; 74c, M = Et₄N, R = Ph, X = NCS) and 75a-d (75a, M = Bu₄N, R = Me, X = Cl; 75b, M = DMP, R = Ph, X = Br; 75c, M = Et₄N, R = Ph, X = I; 75d, M = DMP, R = Ph, X = NCS), exist as ionic species, with the geometries at tin in the anions being TBP with some distortions toward RP structures (Table 15). Chelating DMIT and DMIO ligands are bonded to Sn via dithiolate S atoms in axial and equatorial sites, with an SSnS angle of 95°, while the second axial position is occupied by halogen or NCS group, with the XₐₓSₐₚ bond lengths (2.55–2.66 Å), a larger variation is found for the Sn-Sₐₚ bond lengths (2.55–2.66 Å). There is a particularly narrow range of values for the equatorial Sn-Sₑq bond lengths (2.43–2.46 Å), while a larger variation is found for the Sn-Sₐₚ bond lengths (2.55–2.66 Å). The latter, as well as the axial Sn-Hal or Sn-N bond lengths, are longer than those for their values in tetrahedral derivatives. For example, in the case of the DMIT derivatives 75a-c the Sn–N(CS), Sn–Cl, Sn–Br and Sn–I distances are ca 5, 7, 7 and 9% longer, respectively, than the appropriate sum of the covalent bond radii of 2.15, 2.39, 2.54 and 2.73 Å.

The neutral species MePhSn(DMIT) (77a) is linked into zigzag chains via Sn–S–S interactions. The δ¹ⁱ⁹Sn values recorded for the MX-R₂Sn(DMIT) complexes reflect the average values for rapidly equilibrating R₂Sn(DMIT) and [R₂Sn(DMIT)]⁻ species.

A series of monocyclic halo stannates with mixed oxygen–sulfur ligands, 78a-d, 79, 80, 82, as well as the homo-ligand TDT derivative 81, all containing aromatic ortho-ligand chelated to tin, were obtained by reacting the halide salt with the tetracoordinated stannate precursor in acetonitrile solution. A similar method was used for the preparation of salt [Me₂Sn(S₂N₂)Cl][Ph₄As]. X-ray diffraction of the fluoro 78a, chloro 80 and iodo 79 derivatives revealed TBP structures with the more electronegative oxygen and halogen atoms in the apical positions, with increased distortion as the halogen size increases (Table 15). Thus, the Sn atom in fluoro 78a is only 0.006 Å out of the equatorial plane toward the halogen atom. In chloride 80, the Sn atom is slightly displaced (at 0.076 Å) from the equatorial plane in the direction of the halogen while in the iodo derivative 79 the large Sn atom displacement of 0.178 Å takes place away from the axial iodine atom. The latter forms a weakly coupled dimeric unit formed by intermolecular Sn–S coordination at 2.646 Å.

The most pronounced angular change for this series of halostannates occurs in the CSnC equatorial angle. It increases from 117.6° for fluoro 78a to 130.3° for the chloro derivative 80 and to 140.1° for iodo compound 79.

Unlike chloride 80, the Sn atom in the mono(dithiolato) tin complex 81 is displaced from the equatorial plane toward the axial S atom (but not the axial chlorine). The anion in salt 82 adopts distorted TBP structure with equatorial methyl groups and a long axial Sn–Cl bond (2.652 Å).

The anionic binuclear monocyclic tin derivatives, 83a and 83b, containing ring saturation, were isolated from the reaction of MeSnCl₃ or n-BuSnCl₃, respectively, with Na₂(EDT) in the presence of Et₄NCI (see below).
X-ray investigation shows that the geometry about the tin atom in the dianion of 83a closely approaches the TBP with one of the S atoms and a Cl in axial positions. The $^{119}$Sn NMR data on 83a show a single resonance at $-52.3$ ppm (CH$_3$CN) that is consistent with its five-coordinate tin structures in solution.

It should be noted that the geometries about the Sn atom in the monocyclic stannates can alternatively be viewed as being somewhat displaced from a TBP toward a RP having C$_{eq}$ (compounds 70–73, 75a, 83a, see Tables 14 and 15) or S$_{eq}$ (compounds 78a, 79–81, see Table 15) in the apical (Z) position (Scheme 5).

**b. Lead.** Earlier data concerning organolead dithiolate complexes, namely R$_2$PbL$_2$ (R = Me, Ph; L = EDT, o-S$_2$C$_6$H$_4$, TDT or MNT), [Ph$_3$Pb(MNT)][Ph$_4$As], [Ph$_2$Pb(MNT) Cl][Ph$_4$E] (E = P, As), [(Ph$_3$Pb)$_2$(TDT)], [Ph$_2$Pb(MNT)$_2$][Me$_4$N]$_2$ and [Ph$_3$Pb(MNT)]

SCHEME 5. Relationship between trigonal bipyramid and rectangular pyramid for anionic pentacoordinate monocyclic tin complexes with (a) $\text{Ph}_3\text{Sn}$ and (b) $\text{R}_2\text{Sn}$ frameworks

[Me\textsubscript{4}N], were cited elsewhere\textsuperscript{308}. Compound $\text{Ph}_2\text{Pb(DMIT)}$ (84), which is light-sensitive in solution, was recently prepared from $\text{Ph}_2\text{Pb(OAc)}_2$ and $[\text{Zn(DMIT)}_2][\text{Et}_4\text{N}]_2$\textsuperscript{308}. The $^{207}\text{Pb}$ NMR spectrum (248 ppm, solid state) indicates a coordination number of lead higher than four. The ionic species, $[\text{Ph}_2\text{Pb(DMIT)}\text{I}]\text{[M]}$ (M = Et\textsubscript{4}N, 4-MeC\textsubscript{6}H\textsubscript{4}NMe), were obtained from reaction of $\text{Ph}_2\text{PbI}_2$ with $[\text{Zn(DMIT)}_2][\text{Et}_4\text{N}]_2$ or by addition of $\text{M}\text{I}$ to 84, respectively. An attempt to prepare the anionic triorganolead complex by the reaction of $\text{Ph}_3\text{PbOAc}$ with either Na\textsubscript{2}(DMIT) or $[\text{Zn(DMIT)}_2][\text{Et}_4\text{N}]_2$ yields the neutral compound ($\text{Ph}_3\text{Pb}$)$\textsubscript{2}$ (DMIT) (85). X-ray investigation revealed 85 to be a monomeric compound with each Pb atom having a distorted tetrahedral geometry\textsuperscript{308}.

The monocyclic dithiolato halo plumbates, 86a–c, were synthesized by the condensation of diphenyllead dichloride with toluene-3,4-dithiol in the presence of Et\textsubscript{3}N, followed by the addition of tetraethylammonium halide as shown in equation 15\textsuperscript{327}.

Compounds 86b and 86c are the only representatives of five-coordinated plumbates, whose structures were proved so far by X-ray diffraction. The Pb atoms in the anions of these compounds have a distorted TBP geometry, which is close to the related dithiolato monocyclic tin structures (Table 15). In particular, the $\text{S}_{ax}\text{Mc}_{ax}$ and $\text{C}_{eq}\text{Mc}_{eq}$ angles (M = Pb, Sn) in the chloro derivative 86b and its Sn analogue, 81, are 165.8 and 165.9°, 127.6 and 121.2°, respectively. Thus, in the former the extent of the TBP → RP distortion is greater than for the stannate 81. The arrangement at the central atom in bromide 86c is presumably close to RP when compared with compounds 86b and 81, as evidenced by the values of the $\text{S}_{ax}\text{PbBr}_{ax}$ and $\text{C}_{eq}\text{PbC}_{eq}$ angles (166.2 and 129.9°, respectively)\textsuperscript{327}.

2. Spiro cyclic derivatives

a. Germanium. Two bidentate oxo or related ligands at the central atom form a complex with a spiro arrangement around this atom. The earlier example of such compounds is the hexafluorocumyl alcohol derivatives 87 (R = Me, n-Bu, All, Ph), which were synthesized.
from nucleophilic addition of RLi to the corresponding tetracoordinated precursor, followed by an exchange with Et₄NX. The anion in 87a M = Ge according to X-ray diffraction is primarily TBP as the OGeO angle widens to 173.8° and the internal OGeC angles narrow to an average of 83.4° (see Table 17 below). The Ge–O and Ge–C bond lengths are increased relative to those of the tetracoordinated precursors, with the axial Ge–O bond being lengthened much more than the equatorial Ge–C bonds (average increases ca. 0.2 and ca. 0.05 Å). Two spirocyclic germanium complexes, 88 and 89, both containing HOGeO₄ moiety, were recently described. The former was prepared from germanium dioxide, pinacol and methanol in the presence of sodium hydroxide. X-ray diffraction of 88·3H₂O reveals that the Ge atom in the anion of the sodium derivative has the TBP geometry with one O atom of each bidentate ligand and the hydroxo group in equatorial positions. The other two O atoms of the bidentate ligands are in axial sites (angle 173.5°). The Ge–O(H) bond length (1.769 Å) is slightly shorter than the other two equatorial Ge–O bonds (1.796 and 1.806 Å), which in turn are significantly shorter than the axial Ge–O bonds (1.866 and 1.870 Å), as expected. In contrast, the lithium derivative 89 contains a pentacoordinate germanium in a spirocyclic arrangement as part of a polymer chain due to the O⋯Li contacts, with the Ge atom array having an almost RP structure (the trans-basal angles are 150.7 and 150.2°).

Holmes and his coworkers described a number of pentacoordinated anionic germanium complexes containing a spirocyclic framework with methyl, phenyl, halogen or hydroxyl ligand at the acyclic site. Reaction of an organogermainium trichloride with a catechol or thiocatechol derivative in the presence of triethylamine, followed by a metathetical exchange, led to desired products as illustrated by the formation of the phenyl-substituted derivatives 90 and 91 (equation 16).

Analogously, the tetrachlorocatechol derivative [(o-OC₆Cl₄O)₂GePh][Et₄N] (92), as well as methyl-substituted germanates, namely [(o-OC₆H₄O)₂GeMe][Et₄N] (93) and [(o-OC₆Cl₄O)₂GeMe][Et₄N] (94), were prepared.

(16)

(91)
A number of spirocyclic tetra-, penta- and hexacoordinated germanium complexes have been described in the course of studying interaction between GeCl₄ and catechol, 3,5-di-tert-butylcatechol and toluene-3,4-dithiol in the presence of triethylamine. Among them, the spirocyclic systems, bis(o-phenylenedioxy)germane as a water adduct (o-OC₆H₄O)₂Ge·2H₂O (95) and (TDT)₂Ge (96), are precursors of the neutral and anionic hypervalent germanium compounds. In particular, halogermanates 97a–c were obtained by the reaction of 95 with the corresponding tetraethylammonium halide. Their hydrolytic stability decreases in the order F > Cl > Br.

Unlike catechol, 3,5-di-tert-butylcatechol reacts with GeCl₄ and Et₃N to yield the penta-coordinated 3,5-di-tert-butylcatecholato (DTBC) germanate [(DTBC)₂GeCl][Et₃NH]. The latter gives the corresponding hydroxyl derivative [(DTBC)₂Ge(HO)][Et₃NH] (98) by the action of water.

As for dithiagermanate derivatives, the methyl-substituted compound containing the TDT ligand, 99, was prepared analogously by the reaction given in equation 16 using toluene-3,4-dithiol, triethylamine and MeGeCl. In turn, the air-unstable fluoro-thio germanate [(TDT)₂GeF][Et₄N] was obtained by the reaction of 96 with tetraethylammonium fluoride while the more stable germanate 100 was synthesized by the reaction of 96 with [MePPh₃][Br] and KF.
The synthetic route to the oxo-thio mixed-ligand halo germanates 101a–d\textsuperscript{335} is similar to the synthesis for related oxo derivatives 97a–c\textsuperscript{307,334}. In the first stage the tetracoordinated spirocyclic system is formed. In a following reaction with an appropriate halide reagent the desired product is easily obtained for all of the halides (equation 17)\textsuperscript{335}.

\[
\begin{align*}
\text{GeCl}_4 + 4\text{HCl} & \rightarrow \text{Ge} \underbrace{\text{S}}_{\text{SH}} \underbrace{\text{O}}_{\text{OH}} \\
\text{Et}_4\text{NX} & \rightarrow \text{Ge} \underbrace{\text{S}}_{\text{X}} \underbrace{\text{O}}_{\text{X}}
\end{align*}
\]

(101) (a) X = F  
(b) X = Cl  
(c) X = Br  
(d) X = I

Systematic studies of the distortion coordinate for anionic five-coordinated germanium and tin chelates as a model for nucleophilic substitution have been carried out by Holmes and his coworkers\textsuperscript{316,332,333,335,336}. The Ge atom in spirocyclic germanates varying in the ring composition and the nature of a monodentate ligand lies on the coordinate connecting a trigonal bipyramid (TBP) to a square or rectangular pyramid (RP) having four basal chalcogen atoms (X, Y = O, S) and an apical group Z (Z = Me, Ph, Hal, OH), where Z is pivotal in the Berry pseudorotation process (Scheme 6).

\[
\begin{align*}
\text{Trigonal bipyramid} & \rightarrow \text{Rectangular pyramid} \\
X_{\text{ax}} - M - X'_{\text{ax}} & \rightarrow X_{\text{ax}} - M - X'_{\text{ax}} \\
Y_{\text{eq}} - M - Y'_{\text{eq}} & \rightarrow Y_{\text{eq}} - M - Y'_{\text{eq}}
\end{align*}
\]

M = Ge, Sn; X,X', Y,Y' = O, S; Z = Me, Ph, Hal, OH

SCHEME 6. Relationship between trigonal bipyramid and rectangular pyramid for pentacoordinated spirocyclic germanium and tin complexes

Some geometrical parameters for spirocyclic germanates, including the extents of distortions away from TBP toward RP structure calculated using the dihedral method, initially outlined by Mütterties and Guggenberge\textsuperscript{337} and further developed by Holmes
and his coworkers\textsuperscript{316,328}, have been compiled in Table 17. Large structural variations were reported, between 22.6\% deviation in \textcolor{red}{93} from a near-ideal TBP to an almost perfect RP, with a calculated 95.7\% deviation from TBP in \textcolor{red}{98}. A convenient view of the extents of the structural distortions for pentacoordinated species can be obtained from the changes in the axial and equatorial angles of the TBP, which become the \textit{trans}-basal angles of the corresponding RP. These structural variations are parallel to the progress along the Berry pseudorotation reaction coordinate, in which RP is the assumed transition state.

The unique apical bond becomes shorter, in general, as the pentacoordinated structure more closely approaches the RP in accordance with the VSEPR theory\textsuperscript{334,345}. For example, the Ge–F bond length in \textcolor{red}{97a} (1.727 Å, for TBP $\rightarrow$ RP 80.6\%) is significantly shorter than that in \textcolor{red}{100} (1.780 Å, for TBP $\rightarrow$ RP 40.3\%). Highly electronegative monodentate ligands drive the structure toward the RP geometry. Thus, the extent of approaching to RP increases in the order $\text{Br} < \text{Cl} < \text{F}$ for the most halo germanates, with one exception of the chloro derivative \textcolor{red}{97b}. More electronegative substituents in the bidentate ligand such as tetrachlorocatechol (\textcolor{red}{92} and \textcolor{red}{94}) give an analogous result.

It is noteworthy that the Et\textsubscript{3}NH\textsuperscript{+} salt \textcolor{red}{90} is closer to RP in comparison with the Et\textsubscript{4}N\textsuperscript{+} salt \textcolor{red}{91} due to hydrogen bonding to the cation which lengthens the Ge–O bonds\textsuperscript{333}. Analogously, compound \textcolor{red}{98} with geometry closer to RP contains an apical hydroxyl group that is also hydrogen bonded to the triethylammonium cation\textsuperscript{335}.

When the ring atoms in a spirocyclic system are different as in the mixed-ligand-containing germanates \textcolor{red}{101b} and \textcolor{red}{101c}, the structure tends to be close to the TBP. This is a consequence of the disparity in electronegativity between the ring atoms and the preference for the positioning of the more electronegative ring atom in the axial site of the TBP\textsuperscript{335}. For the most part, however, the structural variations are understandable in terms of substituent effects, and more complete discussions are available elsewhere\textsuperscript{332,333}.

The degree of TBP $\rightarrow$ RP distortions in the spirocyclic anionic and zwitterionic germanates (Section IV.B.3) is rather similar to that observed for the corresponding silicon analogues\textsuperscript{42} for a comparable set of ligands, although as a rule the structures of Si analogues are close to the TBP.

\textit{b. Tin.} A series of the stable anionic tin complexes \textcolor{red}{87}, $M = \text{Sn} (R = \text{Me, Bu, Ph, } p$-$\text{MeC}_6\text{H}_4; R^1 = \text{Me, Et, } n$-$\text{Bu}$), the Sn analogues of germanium hexafluorocumyl alcohol derivatives \textcolor{red}{87}, $M = \text{Ge}$, was prepared by the reaction of their tetracoordinated precursor with RLi followed by an exchange with a tetraalkylammonium halide\textsuperscript{346}. Reaction of \textcolor{red}{87}, $M = \text{Sn} (R = \text{Ph, } p$-$\text{MeC}_6\text{H}_4)$ with SO\textsubscript{2}Cl\textsubscript{2} gave the corresponding chlorostannates \textcolor{red}{87}, $M = \text{Sn} (R = \text{Cl})$, which were converted to fluorostannate \textcolor{red}{87}, $M = \text{Sn} (R = F, R^1 = n$-$\text{Bu})$ by reaction with Bu\textsubscript{4}NF. Its anion has a distorted TBP structure as shown by X-ray crystallography.

Attempts to obtain stable pentacoordinated derivatives bearing only ring Sn–O coordination failed\textsuperscript{316}, in contrast with the predominant formation of ring Ge–O bonding in anionic spirogermanates (see above). In particular, the hexacoordinated dianionic tris(catecholate), [($\text{o}$-$\text{OC}_6\text{H}_4\text{O}$)$_3$$\text{Sn}$][Et\textsubscript{3}NH\textsubscript{2}] (\textcolor{red}{102}), was formed from unstable [$($\text{o}$-$\text{OC}_6\text{H}_4\text{O}$)$_2$$\text{SnPh}$][Et\textsubscript{3}NH] (\textcolor{red}{103}) by hydrolytic scission of the Sn–C(phenyl) bond. Intermediate \textcolor{red}{103} was obtained from phenylstannonic acid and catechol in the presence of Et\textsubscript{3}N\textsuperscript{336}.

More stable mixed-ligand five-coordinated species \textcolor{red}{104a, b} were synthesized by reaction of Sn(OAc)$_4$, with $\text{o}$-mercaptophenol followed by halide salt addition (equation 18)\textsuperscript{336}.

The fluoro stannate \textcolor{red}{104a} like the phenyl derivative \textcolor{red}{103} is not sufficiently stable and gives the hexacoordinated salt [($\text{C}_6\text{H}_4\text{OS}$)$_3$Sn]$_2$[H$_3$][Et\textsubscript{4}N] (\textcolor{red}{105}) upon recrystallization as a result of hydrolysis. Hexacoordination of the tin atoms in \textcolor{red}{102} and \textcolor{red}{105} was proved by X-ray studies\textsuperscript{336}.

16. Hypervalent compounds of organic germanium, tin and lead derivatives

In contrast to homo-ligand oxo spirostannates, pentacoordinated anionic stannates exhibiting only Sn–S bonding with cyclic compounds are well known. This was attributed to the special stability of Sn–S bonding in these compounds provided by a proper balance of low tin atom electronegativity vs. the tendency of Sn to increase its coordination number toward hexacoordinate when Sn–O bonds are present, by virtue of the resultant greater tin acidity. The synthetic procedure used for the preparation of the bicyclic derivatives 106 and 107 containing saturated EDT rings is given in equations 19.

\[
\text{RSnCl}_3 + \text{Et}_4\text{NCl} \xrightarrow{\text{Me}_2\text{CO}} [\text{RSnCl}_4][\text{Et}_4\text{N}] \\
\text{not isolated}
\]

\[
[\text{RSnCl}_4][\text{Et}_4\text{N}] + 2\text{Na}_2(\text{SCH}_2\text{CH}_2\text{S}) \xrightarrow{\text{MeOH}, \text{Me}_2\text{CO}} 4\text{NaCl} + \left[\begin{array}{c}
\text{S} \\
\text{S} \\
\text{Sn} \\
\text{S} \\
\text{S}
\end{array}\right] [\text{Et}_4\text{N}] \\
(106) \text{R} = \text{n-Bu} \\
(107) \text{R} = \text{Ph}
\]

When the same procedure was used with MeSnCl₃, only the binuclear tin species 83a was formed (see above). Moreover, in addition to the mononuclear stannate 106 (equation 19), n-BuSnCl₃ reacts with Na₂(EDT) yielding the binuclear derivative 83b under other conditions (a shorter reaction time, 1 : 1.5 molar ratio). Thus, the formation of the binuclear species 83a,b as intermediates was suggested for reactions leading to the bicyclic stannates 106 and 107.

The bicyclic distannates 108a and 108b were formed presumably as partial hydrolysis products by the reaction of Sn(EDT)₂ with the corresponding amine. The \(^{119}\text{Sn}\) NMR spectra of 107 and 108a in MeCN show single resonances in the range \(-15\) to \(-82\) ppm that are consistent with their five-coordinated tin structures in solution.

The syntheses of bicyclic analogues of the monocyclic 73 containing ring unsaturation, namely stannates 109a and 109b, are similar to those for their saturated EDT derivatives and involve the reaction of organotin trichloride, tetraalkylammonium halide and Na₂(MNT)₃. In the reaction of PhSnCl₃ with Na₂(MNT) and Et₄NCl, Sn–C bond cleavage occurs with formation of the tricyclic stannate [Sn(MNT)₃][Et₄N][Na] (110), most likely as a result of the presence of adventitious water. Unlike in monocyclic 73 which has a near-TBP arrangement about the tin atom, the geometries of the bicyclic stannates 109a and 109b are square pyramidal, while in stannate 110 the geometry is distorted octahedral with an average Sn–S bond length at ca 2.54 Å, which is ca 0.03 Å longer than that for the pentacoordinated 109a and 109b.
The general synthetic route to the other types of pentacoordinated unsaturated spirostan-

ates, namely DMIO 111347 and DMIT 112348,349 derivatives, involves the reaction of an organotin trichloride with the appropriate zinc salt (equation 20).

\]
Among L = DMIO, (L = O), DMIT (L = S) compounds 111 and 112, those containing the ROOCCH₂CH₂Sn moiety, so-called ‘estertin’ compounds, are of particular interest due to the ability of the ROOCCH₂CH₂ unit to act as a chelating ligand utilizing the carbonyl oxygen as an additional donor center. Indeed, as shown by X-ray crystallography, the tin atoms in the anions of 111a and 112d from five strong bonds to carbon and the four thiolato S atoms (Sn−S 2.46 to 2.56 Å). The arrangement of these five bonds about tin is between TBP and RP, but close to the former for 111a and to the latter for 112d (Table 18). There is an additional intramolecular, but weaker, interaction with the carbonyl oxygen atom (Sn−O = 3.11, 3.37 Å, respectively), and tin becomes six-coordinate with a much distorted octahedral geometry. Correspondingly, the ν(C=O) value in the solid state of ca 1714 cm⁻¹ for 111a and 112d is between that for a coordinated and noncoordinated ester group (1670–1680 and 1730–1740 cm⁻¹, respectively). However, the situation for 112c is different from that found for 111a and 112d. In the anion of 112c the ‘estertin’ group acts as a monodentate ligand, with the carbonyl oxygen being directed away from the tin atom (Sn⋅⋅⋅O 4.84 Å), which is more than the sum of the van der Waals radii of Sn and O. This difference can be related to crystal packing effects.

Whereas the DMIO and DMIT ligands in 111a and 112a–d are individually planar, the compounds are not coplanar and the tin atoms are displaced from the basal planes in a direction toward the apical R groups. For example, the angles between the DMIT mean planes in 112a and 112b are 19.2 and 10.8° while the corresponding displacements from the basal plane for these compounds are 0.731 Å and 0.733 Å, respectively. The δ¹¹⁹Sn values of 112a and 112b in CDCl₃ solution are only slightly different than those in the solid state (Table 18). Hence, there are no major changes in the molecular structures on passing from the solid state to solution. Comparison of δ¹¹⁹Sn values for 112b in CDCl₃ and 107 in MeCN (−21.9 and −82.4 ppm, respectively) indicates that the DMIT ligand causes a larger shift to a lower field than that caused by the EDT ligand. In turn, the tin atoms in the spirocyclic DMIO complexes are more upfield shielded than in the DMIT analogues as indicated by comparison of the δ¹¹⁹Sn values for 111a–c and 112c and 112d (ca −50 ppm in CDCl₃, and ca 6.0 ppm in CD₃COCD₃, respectively).

Anionic spirocyclic pentacoordinate tin species having aromatic rings, namely bis(TDT) complexes 113a and 113b, were prepared in high yields by addition of halide ion to bis(toluene-3,4-dithiolato)tin, Sn(TDT)₂, (equation 21).

As in the spirocyclic five-coordinated germanium complexes discussed above, the geometry about the tin atom in some of the mono- and bi-cyclic stannates, listed in

\(^n\) An additional intramolecular Sn–O interaction at 3.371 Å.
Tables 14, 15 and 18, was analyzed as being on the coordinate connecting an ideal TBP with an ideal SP or RP\textsuperscript{316}. The extents of the TBP $\rightarrow$ RP distortions have been quantified using the dihedral method\textsuperscript{316,325,336,348} and from the changes in the axial and equatorial angles of TBP, which become the trans-basal angles of the corresponding RP, as discussed above for the spirocyclic germanates.

Generally, the monocyclic stannates have geometries approaching the TBP (TBP $\rightarrow$ RP, 6–50%), while the geometrical arrangement for the most bicyclic bis(dithiolato) stannates is based on the square or rectangular pyramid (48–97%)\textsuperscript{316}. Comparison of the TBP $\rightarrow$ RP distortions for the monocyclic stannates with Ph$_3$Sn and R$_2$(Hal)Sn frameworks (Tables 14 and 15) indicates that the structures of diphenylhalo tin complexes are less close to a RP (6–24%) than their triphenyltin analogues (30–50%). The extents of the distortion of TBP geometry for the mono- and bicyclic EDT, MNT and DMIT derivatives are close. In the case of spirocyclic stannates, introduction of dissimilar bonding ring atoms, in particular O and S, as in \textsuperscript{104b}\textsuperscript{336}, allows the apicophilicity rule\textsuperscript{350} to take preference over the ring-strain effect and causes structural displacement back to the inherently more stable TBP (TBP $\rightarrow$ RP, 38% for \textsuperscript{104a} as compared 76.9% for \textsuperscript{113a})\textsuperscript{336}.

The axial Sn–S$_{ax}$ bond lengths for the monocyclic stannates (Table 15) are longer than the equatorial Sn–S$_{eq}$ distances (at ca 0.15 Å), of the order expected for trigonal bipyramids\textsuperscript{324}. The differences in the Sn–S bond lengths, $\Delta$(Sn–S), for bis(dithiolato) stannates can be also used as a reflection of the distortions from regular rectangular pyramidal arrays: generally, the smaller the $\Delta$(Sn–S), the closer is the structure to that of a RP. In particular, a residual TBP character is apparent in compounds \textsuperscript{106, 107} and \textsuperscript{108a} in that the Sn–S$_{ax}$ bonds (2.49–2.54 Å) are longer than the Sn–S$_{eq}$ bonds (2.42–2.48 Å)\textsuperscript{325}. The Sn–S$_{ax}$ bond lengths at 2.540 Å found in \textsuperscript{108a} are longer in comparison with those for other stannanes given in Table 18. This is evidently due to S···H hydrogen bonding to the cation which lengthens the corresponding Sn–S bond.

For the spirocyclic tin complexes \textsuperscript{113a} and \textsuperscript{109b}, the Sn–S bond lengths are much closer. They are two shorter ones, averaging 2.458 and 2.521 Å, and two longer ones, averaging 2.455 and 2.516 Å, respectively\textsuperscript{324}. This small difference is indicative of a residual TBP character that was expressed by the ca 94 and 97% displacement toward RP.

For the monocyclic stannates \textsuperscript{106} and \textsuperscript{107}, the Sn–S bond lengths are much closer. They are two shorter ones, averaging 2.458 and 2.521 Å, and two longer ones, averaging 2.455 and 2.516 Å, respectively\textsuperscript{324}. This small difference is indicative of a residual TBP character that was expressed by the ca 94 and 97% displacement toward RP.

In general, solid-state five-coordinated tin structures lie along the Berry pseudorotational coordinate as an expression of their structural nonrigidity. Comparison with other elements of group 14 shows that the nonrigid character increases along the series Si < Ge < Sn as determined by the ease of TBP $\rightarrow$ RP structural distortion\textsuperscript{316,335}. For example, the TBP $\rightarrow$ RP distortions are 80.6 and average ca 61% for the germanium derivative \textsuperscript{97a} and its Si analogue, 40.3, 76.9 and 94.2% for the chloro germanate \textsuperscript{100a} and the halo stannates \textsuperscript{113a} and \textsuperscript{113b}, as well as 34.2 and 38.0% for the mixed-ligand complexes \textsuperscript{101b} and \textsuperscript{104b} (Tables 17 and 18)\textsuperscript{335}.

3. Zwitterionic spirogermanates

Tacke and his coworkers have recently reported the synthesis and structural characterization of a series of pentacoordinated anionic germanium complexes based on the GeO$_4$C ligand framework\textsuperscript{340–344}. The route to these compounds involves the reaction of (chloromethyl)trimethoxygermane with a secondary amine in the presence of triethylamine, followed by an exchange with two equivalents of bidentate ligands, such as aromatic 1,2-diols or $\alpha$-hydroxycarboxylic acids, as shown for the synthesis of \textsuperscript{114} (equations 22 and 23).
The catechol or glycolic acid derivatives, 115a–c and 116a–f, including the dinuclear germanate 117, were prepared similarly.

(115a) NR₃ = NMe₂H  
(115b) R = Me  
(115c) NR₃ = c-HN(CH₂)₂O

(116a) R = Me, R¹ = H  
(116b) R = R¹ = Me  
(116c) R = Me, R¹ = Ph  
(116d) NR₂ = c-N(CH₂)₂O, R¹ = H  
(116e) NR₂ = c-N(CH₂)₂O, R¹ = Me  
(116f) NR₂ = c-N(CH₂)₂O, R¹ = CH₂COOH

(117)
As shown by X-ray crystallography, the coordination polyhedra surrounding the Ge atoms of zwitterionic germanates can be described as more or less distorted TBP with the carboxylate oxygen atoms in axial positions while the carbon atom and two other oxygen atoms occupy equatorial positions. The axial Ge−O distances (1.89–1.92 Å) are significantly longer than the equatorial ones (1.78–1.83 Å). These values as well as the Ge−C distances (1.89–1.92 Å) are similar to the Ge−O and Ge−C distances of related anionic spirogermanates with GeO<sub>4</sub>C frameworks (Table 17). The two chiral TBP germanate units in dinuclear germanate exhibit opposite absolute configurations due to the center of inversion. Consequently, its molecular structure represents the meso configuration.

Like the anionic spirogermanates (Table 17), the geometries at germanium in the zwitterionic germanates can be inspected as being in a region between TBP and SP. In terms of the Berry pseudorotation coordinate, the dihedral angle method shows that the geometries of these coordination polyhedra are displaced by 38.9, 11.4, 14.0 and 13.9% for compounds 114, 116a, 116f and 117, respectively, from the ideal TBP to the ideal SP (pivot atom C). These distortions are rather similar to those observed for the corresponding silicon analogues (TBP → SP: 21, -, 13.4 and 11.5%, respectively).

**V. PENTACOORDINATE INTERMOLECULAR NEUTRAL COMPOUNDS**

**A. Germanium**

While SiCl<sub>4</sub> gives structurally investigated hexacoordinate 1 : 2 adducts with donor atoms from only the III period, for example Cl<sub>4</sub>Si·2PMe<sub>3</sub> (P → Si = 2.26 Å), GeCl<sub>4</sub> produces pentacoordinate 1 : 1 adducts, in particular Cl<sub>4</sub>Ge·NMe<sub>3</sub> (N → Ge = 2.19 Å). The smaller coordination number of the former adducts is most likely due to the smaller size of N compared with the P atom (r<sub>cov</sub> = 0.734 and 1.107 Å, respectively) and, consequently, to a larger steric interaction of the ligands in the germanium coordination sphere.

<sup>73</sup>Ge and <sup>14</sup>N NMR spectra were used to study the reaction products and chemical exchange processes in the system GeCl<sub>4</sub> + KSCN + acetone-d<sub>6</sub>. At a GeCl<sub>4</sub> to KSCN ratio from 2 : 1 to 1 : 4, germanium(IV) derivatives of the type Ge(NCS)<sub>n</sub>Cl<sub>n</sub>−4 were formed. Rapid exchange with Cl and NCS groups due to intermolecular interactions was observed between Ge(NCS)<sub>n</sub>Cl<sub>n</sub>−4 (n = 0–4) molecules with varying n.

**B. Tin**

Hypervalent compounds of organic derivatives of tin with nitrogen- and oxygen-containing ligands have been studied extensively by means of various methods, including X-ray diffraction and <sup>1</sup>H, <sup>13</sup>C and <sup>119</sup>Sn NMR spectroscopy. The conclusions concerning the nature of the D → Sn coordination bonds on going from one complex to another have been deduced as a rule on the basis of direct structural parameters (D → Sn bond lengths) and from the changes of indirect spectral parameters such as δ<sup>119</sup>Sn chemical shifts and <sup>1</sup>J(<sup>13</sup>C−<sup>119</sup>Sn) and <sup>2</sup>J(<sup>1</sup>H−<sup>119</sup>Sn) coupling constants.

1. N → Sn coordination

In Table 19, selected bond distances and angles are reported for intermolecular N → Sn<sub>3</sub>X complexes. All adducts have a distorted TBP configuration with the organic groups in the equatorial position and the more electronegative nitrogen and halide or pseudohalide in the axial positions. The smallest N → Sn distance, and hence the strongest donor...

¹Toward the halide atom.
²Two independent molecules.
³N₂C₃H₃ = pyrazole.
⁴N₂C₄H₄ = pyridaziné.
⁵For another example of a pentacoordinate ditin complex, 2,6-(i-Pr)₂C₆H₃N(SnMe₂Cl)₂ · Pyr, which contains one bridged chlorine atom, see Reference 355b.

interaction, is found in the derivatives showing the lowest ΔSn. There is also a correlation related to the hypervalent N → Sn−Hal axis in the two independent molecules of entries 2, 3, 7 and 8 in Table 19: as the N → Sn distance becomes shorter, the Sn−X bond tends to become longer.

For compounds [(p-Tol)₃SnHal]₂ · 4, 4’-Bipy, where Hal = Cl (entry 5), Br (9) and I (10), the deviation (Δ) of the tin atom from the equatorial plane decreases on increasing the electron-withdrawing effect of the substituent X: ΔSn(Cl) < ΔSn(I and Br) (Table 19). However, for the pair Br and I this is not true. The same anomaly for I and Br atoms was observed in the coordinate bond length in the range N → Sn(Cl) > N → Sn(I) > and N → Sn(Br).

In two independent molecules of ClPh₃Sn · 1-methylimidazole (NMI, entry 3), one tin atom is displaced by 0.307 Å out of the imidazole plane, whereas the other tin is almost coplanar with the plane of the imidazole donor. Differences in coordination geometries of ligands as well as nonsystematic variations in N → Sn−X angles can be ascribed to crystal packing effects.

The ¹¹⁹Sn NMR spectra of triorganotin(IV) adducts exhibit a single absorption typical of four- to five-coordinate central tin atom. For example, the signals for (1-BzIm)Me₃SnCl (δ¹¹⁹Sn = −14.5 ppm, CDCl₃) and (1-BzIm)Ph₃SnCl (δ¹¹⁹Sn = −125.9 ppm) are shifted upfield with respect to those reported for the starting acceptor (δ¹¹⁹Sn = 154.3 ppm and −48 ppm, respectively).

In diorganotin adducts D → SnR₂X₂ the Sn−X bond length differences between axial and equatorial positions in the pentacoordinate species 118 are of particular interest since they conform quite well to expectations of hypervalent D → Sn−X bonding (Section V.B.3). The longer Sn−Clax bond length by ca. 0.06 Å due to N → Sn donor interaction is consistent with the expected lower s character of the axial bond compared to...

those of the equatorial bond (Table 20). The tin atom in all adducts is displaced from the least-squares plane defined by the equatorial chloride and carbon atoms in the direction of the axial chloride by an almost identical distance $\Delta \text{Sn} = 0.32$ Å.

An adduct having a composition most closely represented as $\text{SnPh}_2\text{Cl}_2 \cdot \text{Pyz}/(\text{SnPh}_2\text{Cl}_2)_2 \cdot \text{Pyz}$ has a structure composed of layers in which polymeric chains with six-coordinate tin alternate with layers containing noninteracting $\text{SnPh}_2\text{Cl}_2 \cdot \text{Pyz}$ molecules with five-coordinate tin$^82$ (Table 20). The interaction of imidazoles with $R\text{SnX}_3$ proceeded similarly to that with $R_2\text{SnX}_2$. The major difference is the ligand since not only 1 : 1 and 2 : 1 but also 3 : 1 and 3 : 2 adducts can be obtained, depending on the reaction conditions$^{362}$.

2. $O \rightarrow \text{Sn}$ coordination

Tables 21 and 22 provide structural parameters for neutral aqua-triorganotin adducts. The longest tin-water distance of 2.500 Å is found for the 3-pyridylacrylato derivative (Table 21, entry 9). The coordinate bond of 2.253 Å in $\text{SnPh}_3(\text{SCN})$ (entry 10) is the shortest. The strengthening of the $O \rightarrow \text{Sn}$ bond in compounds with the same $\text{SnR}_3$ groups is accompanied by an increase in the tin pyramidalization. This is reflected in the corresponding decrease in the deviation of the tin atom from the equatorial plane ($\Delta \text{Sn}$) of the neighboring carbon atoms.

X-ray diffraction studies on hydrated triorganotin compounds $\text{H}_2\text{O} \rightarrow \text{SnR}_3\text{X}$ have provided several examples of water engaged in inner-sphere coordination to tin in five-coordinate molecules. For inner-sphere coordination, the complexes tend to pack in arrangements in which the number of hydrogen bonding interactions involving the coordinated water molecule is maximized. For example, $o$-phenanthroline monohydrate, which chelates to a plethora of transition metals, forms with triphenyltin chloride an outer-sphere coordination complex in which the coordinated water molecule [O $\rightarrow$ Sn = 2.42 Å]

X$^9$ = 1,3-Dioxisoindoline-2-acetato-O.

$^b$In the direction opposite to H$_2$O.

$^c$XH = Saccharin.
$^d$The coordinated water forms hydrogen bonds to the nitrogen atoms of two 1,10-phenanthrolines.
$^e$R$_3$ = (4-CIC$_6$H$_4$)Ph$_2$.
$^f$The coordinated water forms hydrogen bonds to the two nitrogen atoms of 3,4,7,8-tetramethyl-1,10-phenanthroline.

is linked by hydrogen bonds (O···N = 2.96 and 3.02 Å) to two 1,10-phenanthroline bases$^384$. The molecule crystallizes as a centrosymmetric dimer in which the heterocycles are positioned midway between the two aqua-chlorotriphenyltin entities$^384$. The heterocycle also yields isostructural dimeric complexes with tri-p-chlorophenylnitride$^384$ and triphenyltin trifluoroacetate$^385$.

Addition of four methyl substituents to the 1,10-phenanthroline ligand increases the basicity of its N atoms, enhancing the propensity for hydrogen bonding with the water
of the aqua-chlorotriphenyltin molecule. Thus, the outer-sphere coordination complex of aqua-chlorotriphenyltin with 3,4,7,8-tetramethyl-1,10-phenanthroline (Table 21, entry 20)\textsuperscript{381} has much shorter hydrogen bonds (O···N = 2.661 and 2.767 Å) with aqua-chlorotriphenyltin than does 1,10-phenanthroline. This suggests that electronic factors can influence the formation of these outer-sphere complexes. Both electronic effects and packing forces probably account for the monomeric nature of aqua-bromotriphenyltin o-phenanthroline.

In the crystal structure of pyrazolone derivatives (Table 21, entry 8), the bond length between H\textsubscript{2}O and Sn is longer (2.42 Å) and the distortion from the ideal TBP geometry (the O−Sn−O axis is bent to 174.8°) is probably due to steric hindrance of the 4-acyl-5-pyrazolonate ligand. In chloroform solution, the adduct loses the molecule of water and adopts a tetrahedral arrangement\textsuperscript{369}.

Triorganyltin halides and pseudohalides form stable five-coordinate adducts with the donor oxygen atom of a strong ligand, such as C=O (Table 23), P=O (Table 24), S=O (Table 25), N=O (Table 26) and As=O (Table 27), which have almost TBP geometry at tin.

That the chlorotriorganotin(IV) adducts with carbonyl (Table 23) are invariably five-coordinate rather than six-coordinate has been attributed to steric crowding by the organic groups attached to the tin atom\textsuperscript{253,422a}. Structural study on the R\textsubscript{3}SnCl·L adducts, L = 1-[(4-methylphenylimino)methyl]-2-naphthol and R = Me\textsuperscript{422b} and Ph\textsuperscript{422c}, has revealed that the electronic effect outweighs the steric effect in the formation of the five-coordinate trimethyltin adduct.

The five-coordinate triphenylphosphine oxide and HMPA complexes of triorganotins (Table 24) adopt the common trans-TBP geometry at the Sn atom. The presence of HMPA in the axial position and aryl groups in the equatorial positions promotes a decrease in the ΔSn value, and consequently, approach to ideal TBP configuration. The elongation of the Sn−X distance is due to the hypervalent bond character in the O → Sn−X axial fragment. For example, the Sn−Br bonds of 2.57–2.75 Å are lengthened relative to the bond of 2.295 Å in the parent triphenyltin bromide\textsuperscript{189}.

ᵃCompounds according to entries: 1, nitrato-(triphenylarsineoxide)triphenyltin; 2, isothiocyanato-(triphenylarsineoxide)tribenzyltin; 3, (µ₂-coumarin-3-carboxylato)-(coumarin-3-carboxylato)hexaphenyltriphenylarsineoxide-ditin; 4, (µ₂-1,2-bis(diphenylarsoryl)-ethane-O, O’)-bis(chlorotriphenyltin).

ᵇThe sum of the CSnC equatorial angles.

ᶜIn the direction opposite to As=O.
The crystal structure of the complex \( \text{o-C}_6\text{H}_4(\text{SnClMe}_2)_2 \cdot (\text{Me}_2\text{N})_3\text{PO} \) (entry 2) confirms the conclusion drawn from the low-temperature \( ^{119}\text{Sn} \) NMR measurement. The HMPA molecule acts as a monodentate donor toward one Sn atom, which is displaced from the plane by 0.023 Å in the direction of Cl\( ^{398} \). The O \( \rightarrow \) Sn distance of 2.236 Å is comparable with the O \( \rightarrow \) Sn distances of 2.211 and 2.256 found for related complexes (Ph\( _2\)ClSn\( _2\)CH\( _2 \cdot (\text{Me}_2\text{N})_3\text{PO} \) (entry 1)\(^{397} \) and (Ph\( _2\)ClSnCH\( _2 \cdot (\text{Me}_2\text{N})_3\text{PO} \) (entry 3)\(^{269} \), respectively.

Adduct formation of triethylphosphine oxide (TEPO) with Ph\( _2\)BrSn(CH\( _2 \)\( _n\)SnBrPh\( _2 \), where \( n = 6, 10 \) and 12, and \( (\text{n-C}_4\text{H}_9)\text{SnO}_2\text{C(CH}_2\text{)}\text{pCO}_2\text{Sn(}-\text{n-C}_4\text{H}_9)\text{)} \), where \( n = 2, 6, 10, 12 \) and 14, was monitored by \( ^{31}\text{P} \) NMR. Equilibrium constants for the former were approximately independent of the chain length from \( n = 6 \) to 12, while for the carboxylates the constants for \( n = 2 \) and \( n = 14 \) were small. Equilibrium constants for the intermediate chains were approximately the same. Solid state NMR shows that the adduct is probably not symmetrically chelated\(^{408} \).

The P=O \( \rightarrow \) Sn bonds in phosphine oxide complexes (Table 24) are somewhat shorter than those found in the same carbonyl (Table 23), sulfoxide (Table 25) and N-oxide (Table 26) complexes, reflecting the greater Lewis basicity of the former.

Organotin compounds with intermolecular S=O \( \rightarrow \) Sn interaction are relatively rare and only a few single-crystal X-ray crystal structure analyses have been reported (Table 25). A structure for bis(triphenylstannyl)sulfite, \([\text{Ph}_3\text{Sn}]_2\text{SO}_3\text{TBP}\) (entry 1)\(^{118} \), contains pentacoordinated tin atoms.

The Sn atom in the quinoline-N-oxide derivative (Table 26, entry 7) shows trans-C\( _5\text{SnO}_2\) TBP coordination [\( \Sigma\text{C}=\text{Sn}=\Sigma\text{C}=357.5^\circ \), O \( \rightarrow \) Sn \( =\)0 171.4°]\(^{417} \), but the O \( \rightarrow \) Sn bond of 2.446 Å is much longer than that (2.319 Å) found in the quinoline N-oxide complex of the benzothiazolone derivative (entry 2)\(^{414} \).

Among triorganotin compounds, coordination higher than four at tin is not often realized when a sulfur atom is linked covalently to the metal atom. The structure of triphenyltin isopropylxanthatoquinoline N-oxide (Table 26, entry 8) represents an unusual example of a Lewis-acidic organotin sulfido compound. The geometry of the tin atom is a distorted trans-C\( _5\text{SnOS} \) TBP (O \( \rightarrow \) Sn = 2.448, Sn–S = 2.544 Å; O \( \rightarrow \) Sn–S = 167.4°)\(^{418} \). The oxygen \( \rightarrow \) tin bond distance compares well with those found in the quinoline N-oxide adducts of the triphenyltin derivatives of benzothiazol-3(2\( H \))-one 1,1-dioxide (entry 2) (O \( \rightarrow \) Sn = 2.319 Å)\(^{414} \) and with that (2.459 Å) found in tri-\( p\)-tolyltin bromide quinoline N-oxide\(^{423a} \). The Sn–S distance of 2.544 Å in the xanthate complex is longer than that (2.445 Å) in the parent Lewis acid\(^{423b} \) molecule. Triphenyltin isopropylxanthate itself shows a distorted tetrahedral geometry as a result of an intramolecular contact of 2.950 Å; the Sn–O interaction is apparently preferred to an Sn–S interaction.

In general, the halides Sn\( _n\)X tend to form pentacoordinate adducts with oxygen-containing ligands, but the Sn\( _n\)X\( _2 \) and SnRX\( _3 \) tend to form hexacoordinate adducts (Section X.A). Only a few crystallographic data are available for the former case (Table 28) that confirms the Sn–X bond length difference between axial and equatorial positions in the pentacoordinate species\(^{118} \). The complexes SnPh\( _2\)Cl\( _2 \cdot \text{OPPh}_3 \) and SnPh\( _2\)Br\( _2 \cdot \text{OPPh}_3 \) (entries 1 and 2) are isostructural and replacement of chloride by bromide has remarkably little effect on the angles about tin; the biggest change was recorded in the O \( \rightarrow \) Sn–X (X = Cl or Br) bond angle, which increases by 1.6°. The bond parameters of the phosphine oxide to SnPh\( _2\)Cl\( _2 \) and SnPh\( _2\)Br\( _2 \) are remarkably constant despite the difference in Lewis acidity of the organotin species\(^{424} \).

In a hydrogen-bonded adduct of aqua-dichlorodiphenyltin(IV) (entry 3), the Ph\( _2\)Sn(H\( _2\)O)Cl\( _2 \) unit exhibits a distorted TBP coordination geometry around tin\(^{425} \). The distortion is illustrated by the deviation of the axial O \( \rightarrow \) Sn–Cl bond angle (172.3°) from linearity.

</table>

$^a$D$_1$ = Ph$_2$Sn(2-OC$_{10}$H$_6$CH=NCH$_2$COO).

The axial Sn–Cl bond length (2.469 Å) is considerably longer than the equatorial Sn–Cl bond length (2.338 Å).

Mono-aqua adducts of dimethyltin dichloride with [Ni$^{II}$L]·H$_2$O [H$_2$L = N,N’-bis(3-methoxysalicylidene)ethylenediamine] and N,N’-bis(3-methoxysalicylidene)propane-1,2-diamine] have different structures. In the former the tin is in a TBP environment, whereas in the latter it is in an octahedral environment as a result of an intermolecular Cl···Sn contact of 3.615 Å$^{426}$.

A new dinuclear tin complex, [Ph$_2$Sn(2-OC$_{10}$H$_6$CH=NCH$_2$COO)]SnPh$_2$Cl$_2$ (entry 5), was characterized as a 1 : 1 adduct between the diorganotin dichloride and bicycloazastannoxide with the O → Sn bond distance being 2.307 Å. The TBP geometry of the Sn is distorted as indicated by the O → Sn–Cl bonding angle of 176.6°$^{427}$.

Structure 119 is doubly bridged by the methylene carbon and the oxygen of DMSO, with each Sn atom displaying distorted trigonal-bipyramidal geometry. The bridging methylene group is in the equatorial position in both the Sn$^1$ and Sn$^2$ coordination while the bridging oxygen atom occupies an axial position in both cases. The second apical position is occupied by the Cl$_1$ and Cl$_2$ atoms for Sn$^1$ and Sn$^2$, respectively. The equatorial Sn$^1$–Cl$_3$ distance of 2.372 Å is significantly shorter than the axial distance Sn$^1$–Cl$_1$ of 2.410 Å, trans (174.2°) to the O → Sn bond, 2.572 Å$^{428}$.

Adducts of SnR$_2$X$_2$ appear to be structurally more complex than their triorganotin analogues. Compounds O{(t-Bu)$_2$SnO)$_2$E·(t-Bu)$_2$Sn(OH)$_2$ (E = SiMe$_2$$^{429}$, SiPh$_2$$^{94}$, BMes$^{430}$ and CO$^{94}$) display a unique tricyclic structure 120 consisting of fused six-membered Sn$_2$EO$_3$ and four-membered Sn$_2$O$_2$ rings to form a planar ESn$_3$O$_4$ skeleton, with distorted trigonal-bipyramidal coordination at tin. In the former the distortion of the
axial hypervalent $O \rightarrow Sn^{1,2}$—O bonds is not so great, $O \rightarrow Sn = 2.274$ and 2.279 Å, $Sn-O = 2.006$ and 2.000 Å, $O \rightarrow Sn-O = 163.5$ and 163.6°, respectively.\(^{429}\)

$N$-Methylpyrrolidinone (NMP) is able to react as a bidentate ligand, but a 1 : 2 complexation by dimethyltin dichloride leads to two different pentacoordinated adducts with monodentate NMP ligand.\(^{2183}\) Atom $Sn^1$ has apical ligands with an angle of 177.35° ($O \rightarrow Sn^{1-Clax}$) close to the ideal angle of 180°.\(^{183}\) The $O \rightarrow Sn^1$ bond length (2.278 Å) is shorter and the axial $Sn^1-Clax$ bond (2.570 Å) is longer than in other pentacoordinated diorganotin complexes. The long axial $Sn^1-Clax$ bond in this compound may be caused by its bridging character due to its participation in the second hypervalent bonding $O \rightarrow Sn^{1-Clax} \rightarrow Sn^2-Cl$. Also, the axial $Sn^1-Clax$ bond is long compared with that in other complexes containing bridging $Cl$ ligands such as $Me_3SnCl$\(^{162}\) and $Me_2SnCl_2$\(^{171}\).

The interactions between diethyltin dichloride and pyrimidine nucleotides (5'-CMP, 5'-dCMP and 5'-UMP) in aqueous solution were investigated by multinuclear 1D and 2D NMR techniques including $^{119}Sn$, $^{15}N$ and $^{31}P$ nuclei. At pH values higher than 2.0–3.0, the $Et_2Sn$ moiety of the $Et_2SnCl_2$ is involved in bonding with the phosphate group of the three nucleotides studied. Around neutral pH (5.5–9.0), there is no evidence for interaction of the $Et_2Sn$ moiety with the nucleotide. In a 1 : 1 nucleotide/$Et_2SnCl_2$ mixture at pH > 9.0, $Et_2SnCl_2$ reacts with the two oxygen atoms of the sugar unit of the nucleotide.\(^{431}\)

In general, the halides $RSnX_3$ tend to form hexacoordinate complexes (Section X.A) and pentacoordinate ones are rare. In adduct $MeSnBr_3 \cdot DMF$, the axial $Sn-Br$ bond (2.576 Å) is considerably longer than the equatorial bond (2.475 Å) due to the coordinate $O \rightarrow Sn$ bond (2.28 Å) with the near to ideal linear $O \rightarrow Sn-Brax$ bond angle of 179.2°.\(^{432}\)

The $^{119}Sn$ chemical shift of trichlorobutyltin mixed with 1 equiv of methanol in CDCl$_3$, was at $-181$ ppm with respect to the uncoordinated molecule ($-141.2$ ppm), which confirmed the pentacoordination. In esters, intermediate values may suggest an equilibrium between tetra- and pentacoordinated species, or a weak coordination. Besides, the $^1J(SnC)$ for butyltin trichloride in CDCl$_3$, where the metal is tetracoordinated, is 648 Hz in comparison with 939 Hz in the presence of 1 equivalent of methanol.\(^{433}\)

The coordination geometry of each tin atom in [($H_2O$)Cl$_3Sn(CH_2)_4SnCl_3(OH_2)$] is distorted TBP, with the Sn atom lying 0.270 Å out of the equatorial plane in the direction of the Cl atom in an axial hypervalent fragment $O \rightarrow Sn-Clax$ (bond angle 172.7°).\(^{434}\) The bonds between tin and the chlorine in the equatorial plane (2.330, 2.319 Å) are shorter than the axial bond (2.438 Å). The structure is similar to that found in $[MeOCH_2CH_2O(CH_2)_3SnCl_3( OH_2)]^+$, except that in the latter there is a close intramolecular $Sn \cdots O$ contact of 2.442 Å leading to a distorted octahedral geometry.

3. P → Sn coordination

Much attention has been focused on the nature of P → Sn coordination bonds in phosphines as ligands. The shift of the $^{119}Sn$ resonance to higher field upon adduct formation, the multiplicity of the resonance, the variation of $^{31}P-^{119}Sn$ coupling with the nature of the substituent and the change in the shape of the signals with concentration and temperature were used to determine the stoichiometry and the structure of the phosphine adducts of $Ph_3SnCl$, $R_2SnCl_2$ ($R = Et, Pr, Bu, t-Bu$ and $Ph$) and $RSnCl_3$ ($R = Bu$ and $Ph$)\(^{436}\).

The triorganotin chloride adducts readily exchange with base or with other adducts. The diorganotin dichlorides form only 1 : 1 adducts with tributylphosphine, even at high base to acid ratios. The lower dialkyltin dichlorides prefer to form 1 : 1 adducts (at 1 : 1 mole ratios) with tributylphosphine rather than tributylphosphine oxide (TBPO), whereas
diphenyltin dichloride and di(t-butyl)tin dichloride prefer TBPO adduct formation. The reactions of the trihalides with tributylphosphine and TBPO are complicated by aryl transfer or displacement of chloride by base and a consequent ion formation\(^{356}\).

Interaction of \(RSnHal_3\) and \(SnHal_4\) (Hal = Cl, Br) with monodentate tertiary phosphines (D = Pr\(_3\)P, Bu\(_3\)P, Ph\(_3\)P, Ph\(_2\)MeP and PhMe\(_2\)P) has been studied by \(^{119}\)Sn and \(^{31}\)P NMR spectroscopy in CH\(_2\)Cl\(_2\) at various ratios and temperatures of \(-90^\circ C\) and \(+30^\circ C\).\(^{26,27}\). Multiplicities of \(^{119}\)Sn NMR spectra are in good accord with formation of mainly hexacoordinate complexes\(^{26}\). It was found that equilibria take place in solutions of SnHal\(_4\) and 1 : 1 complexes are formed preferably at excess of the acceptor (A). NMR spectral parameters for the pentacoordinate complexes in CH\(_2\)Cl\(_2\) are given in Table 29.

Detailed analysis of the \(\delta^{119}\)Sn and \(\delta^{31}\)P values for SnCl\(_4\)–Bu\(_3\)P system shows an alternative mechanism for the complexation. An ionic \((SnCl_3 \cdot 2Bu_3P)^+SnCl_5^-\) complex with formal 1 : 1 stoichiometry is formed in excess of SnCl\(_4\) (D/A = 0.5) and at \(-90^\circ C\). On increasing the temperature to \(+30^\circ C\), an irreversible transformation of \((SnCl_3 \cdot 2Bu_3P)^+SnCl_5^-\) into SnCl\(_4\)·Bu\(_3\)P was observed. The complex SnCl\(_4\)·Bu\(_3\)P was transformed into Bu\(_3\)PCI\(^+\)·SnCl\(_5\)\(^-\) and SnCl\(_2\) at room temperature in several hours due to an oxidation–reduction process. Formation of either ionic or molecular complexes has been shown to be characteristic for other phosphines (Me\(_2\)PhP, MePh\(_2\)P)\(^{26}\).

Concentration and temperature dependencies of the NMR spectra of the SnBr\(_4\)–Bu\(_3\)P system shows that only AD\(_2\) complexes exist in solutions at \(-90^\circ C\) regardless of the D/A ratio. In this case there are no ionic structures due to the lower Lewis acidity of SnBr\(_4\). A temperature increase at D/A < 2 leads to dissociation of SnBr\(_4\)·2Bu\(_3\)P into SnBr\(_4\)·Bu\(_3\)P, which transforms immediately and much faster than the analogous SnCl\(_4\) complex into Bu\(_3\)PBr\(^+\)·SnBr\(_5\)\(^-\) due to an oxidation–reduction process\(^{26}\).

**TABLE 29.** \(^{31}\)P and \(^{119}\)Sn NMR parameters for the 1 : 1 SnHal\(_4\) complexes with tertiary phosphines in CH\(_2\)Cl\(_2\) at \(-90^\circ C\).\(^{26}\)

\(^a\)The sum of the CPbC equatorial angles.

\(^b\)L = diphenylcyclopropenone.
C. Lead

The organolead complexes contain few examples of monomeric neutral adducts (Table 30). The structure of \( \text{Ph}_3\text{PbBr}(\text{OPPh}_3) \) shows that the OPPh\(_3\) molecule (O \( \rightarrow \) Pb = 2.556 Å) and the bromine atom (Pb–Br = 2.754 Å) are both at the axial positions displaying hypervalent bonding for the lead atom. The other adducts have the same five-coordinate structure with the three equatorial phenyl groups.

VI. PENTACOORDINATE INTRAMOLECULAR NEUTRAL GERMANIUM COMPOUNDS

A. Monocyclic Complexes

1. Derivatives with bidentate C,O-chelating ligands

Among neutral pentacoordinate intramolecular germanium complexes, compounds containing a C,O-chelating ligand have been most extensively studied.

   a. Compounds with 8-(methoxynaphthyl) ligand. A series of 8-(methoxynaphthyl) germanium derivatives with intramolecular interaction between the germanium and the methoxy oxygen atom were described recently. The initial diorganodichloro- and organotrichlorogermanes were prepared from aryltrichlorogermanes and organolithium reagents or by an organomagnesium route. Their reduction by LiAlH\(_4\) gave the expected organogermanes \( \text{121} \) and \( \text{122} \) (Scheme 7\(^{439--441} \)).

   An X-ray crystallographic study of \( \text{121c} \) revealed a weak intramolecular O \( \rightarrow \) Ge interaction (2.75 Å) and the absence of intermolecular O \( \cdots \) Ge contacts\(^{441} \). The O–Ge distance observed is longer than that of the corresponding covalent bond but appreciably less than the sum of the van der Waals radii (Table 1). The Ge atom retains its tetrahedral geometry, though slightly deformed, with the two hydrogen atoms occupying equatorial positions and the OGeC(Mes) angle at 175.2°. It is noteworthy that in the case of diorganogermane \( \text{124} \) with two 2-methoxyphenyl ligands (equation 24), an intramolecular O \( \cdots \) Ge interaction is not observed\(^{439} \).

\[
\begin{align*}
\text{OMe} & \quad \text{MgBr} \quad \text{GeCl}_4 \quad \text{OMe} \\
\text{2} & \quad \text{GeCl}_2 \quad \text{LiAlH}_4 \quad \text{GeH}_2 \\
& \quad \text{(124)} \quad \text{(24)}
\end{align*}
\]

Reaction of the (8-methoxynaphthyl)germanes \( \text{121} \) and \( \text{122} \) with CF\(_3\)SO\(_3\)H in diethyl ether or with I\(_2\) in benzene yields the corresponding germanium triflates and iodides \( \text{123a–e} \) (Scheme 7). They are air-sensitive powders, insoluble in common hydrocarbon solvents but soluble in CH\(_2\)Cl\(_2\) and CHCl\(_3\)\(^{441} \). Treatment of the triflate \( \text{123c} \) with Lewis bases B(H\(_2\)O, DMSO, C\(_6\)H\(_5\)CH\(_2\)NH\(_2\)) leads to the formation of the corresponding 1 : 1 cationic complexes \( \text{123c} \cdot \text{B} \) (equation 25). According to X-ray data, the geometry at germanium in both the triflate \( \text{123c} \) and the complex \( \text{123c} \cdot \text{H}_2\text{O} \) is close to TBP; the structure of the latter is dimeric (Section VIII.A).

Hydrolysis of compounds \( \text{123a–e} \) by excess of water in the presence of Et\(_3\)N gives germoxanes \( \text{125} \) (R = H, Ph, (8-MeO)Np) instead of the expected germanols. Reaction
SCHEME 7. Synthesis of the 8-(methoxynaphthyl)germanium derivatives 121–123
of iodide $^{123e}$ with NaBPh$_4$ in CH$_3$CN leads to elimination of MeI and formation of germoxolene $^{126}$ instead of the expected anionic product.

$$\begin{align*}
\text{(123c)} & \quad \text{B (B = C}_6\text{H}_5\text{NH}_2, \text{H}_2\text{O, DMSO)} \\
\text{(123c-B)} & \quad \text{OTf}^-
\end{align*}$$

$^{123c}$

Formation of the mono- and dilithium derivatives from the diorganogermanes $^{121, 122}$ and $^{124}$ and $n$-BuLi or $t$-BuLi and their further reactions were discussed$^{442}$. In particular, for the monolithium derivatives $^{121b}$ and $^{121c}$ the authors suggest the structure $^{127}$ having a pentacoordinated Ge atom and intramolecular Li···OMe interaction$^{439}$.

As shown by X-ray crystallography, the geometry at Ge in triflate $^{123c}$ is very close to TBP, with the two 8-methoxynaphthyl ligands and the hydrogen atom forming the central plane. The axial positions are occupied by one methoxy group and the triflate group (the O(OMe)GeO(Tf) angle is 174.9°). The corresponding O—Ge distances, 2.357 and 1.988 Å, are longer than the standard O—Ge bond length (1.76 Å) in four-coordinate compounds$^9$ but are appreciably shorter than the sum of van der Waals radii (Table 1).
16. Hypervalent compounds of organic germanium, tin and lead derivatives

The deviation of the Ge atom from the equatorial plane defined (ΔGe) by the hydrogen and two carbon atoms is 0.166 Å in the direction of the oxygen atom of the triflate group. This contrasts drastically with the structural data for triflate L₆GeMe₂OTf (L₆ = 1-methyl-2-piperidinone) discussed below, for which the (C=O)O–Ge and Ge–O(Tf) distances are 1.90 and 2.58 Å, respectively, and ΔGe = −0.18 Å, which means a displacement toward the carbonyl oxygen.

The second methoxy group seems almost not linked to the germanium atom (the O···Ge contact is 2.799 Å). This is in agreement with the nonequivalence of the methoxy group signals in the ¹H NMR spectra of compounds 123c and 123e at low temperature. At higher temperatures an exchange process at the germanium center averages the NMR signals. The energies of activation of this process (10.5 and 10.8 kcal mol⁻¹, respectively) suggest a dissociative mechanism including rapid interconversion of the chelating groups.

The Ge–H bond (1.33 Å) in 123c is significantly shorter than that in usual four-coordinate compounds (1.52 Å)⁹. Taking into account a similar shortening of the Si–H bond observed in the case of silylum cation stabilized by amino group ⁴⁴³, as well as the high electroconductivity of triflate 123c in CH₂Cl₂ solution and the significantly high frequency shift of the ¹H NMR Ge–H resonances in compounds 123a–e as compared with their neutral precursors (Δδ = +1.45 to 2.06 ppm), a substantial positive charge is localized on the germanium atom ⁴⁴₁.

The unusual hydrated germyl cation structure of complex 123c·H₂O is discussed in Section VIII.A.

b. β-Germyl-substituted derivatives of carboxylic acids and ketones. These O–Ge chelate complexes containing a five-membered chelate ring GeCCCO have been studied extensively by Mironov and coworkers in 1980–1990 ⁴⁴⁴. Reaction of HGeCl₃ with α,β-unsaturated carboxylic acids⁴⁴⁵, esters⁴⁴⁶ or amides⁴⁴⁷ leads to the corresponding β-trichlorogermyl derivatives Cl₃GeCHR(X)R′COX (X = OH, OAlk, NH₂, NAlk₂; R,R′ = H, Me), e.g. compounds 128a–e (equation 26)⁴⁴⁶–⁴⁴⁹.

\[
\begin{align*}
H₂C\equiv C\equiv C\equiv O &\quad \xrightarrow{\text{HGeCl}_3} \quad O\equiv C\equiv C\equiv X \\
R &\quad \xrightarrow{\text{Cl}₃\text{Ge}R} \quad \xrightarrow{\text{Cl}} \quad \xrightarrow{\text{Cl}} \quad \xrightarrow{\text{Ge}} \quad \xrightarrow{X} \\
\text{(128a)} &\quad X = \text{OH}, R = \text{H} \\
\text{(128b)} &\quad X = \text{OH}, R = \text{Me} \\
\text{(128c)} &\quad X = \text{OMe}, R = \text{Me} \\
\text{(128d)} &\quad X = \text{NH₂}, R = \text{H} \\
\text{(128e)} &\quad X = \text{NMe₂}, R = \text{Me}
\end{align*}
\]

(26)

Germylated steroids 129a and 129b were recently prepared by the same method⁴⁵⁰. Imide 128f (R = H, X = NMeCOMe) was obtained by treatment of Cl₃GeCH₂CH₂COCl with MeCONMeSiMe₃⁴⁵¹.
Reduction of GeCl₄ by disiloxane (Me₂SiH)₂O in the presence of a target organic compound (e.g. esters of acrylic acid, etc.) as a solvent is a convenient one-pot alternative to the reaction in equation 26.⁴⁴⁶

Tribromogerme was also used in an analogous reaction to equation 26 for the preparation of β-tribromogermyl analogues of compounds 128 including acids Br₃GeCH₂CHMeCOOH (130a), (Br₃Ge)₂CHCH₂COOH (130b) and ester Br₃GeCH₂CHMeCOOMe (130c).⁴⁵² According to NQR ⁷⁹,⁸¹Br spectra, a weak O → Ge coordination is present in the latter but not in the former compounds.⁴⁵³ X-ray crystallography of 130b confirmed a tetrahedral environment of the Ge atom.⁴⁵⁴

Reaction of the acids 128a and 128b with excess of PhMgBr leads to the corresponding triphenylgermyl derivatives Ph₃GeCH₂CHRCOOH (131) (R = H, Me) where intramolecular O → Ge coordination is absent.⁴⁵⁵ However, the high reactivity of these compounds and the formation of tertiary alcohols in their reactions with Grignard reagents suggest an effective intramolecular assistance in such transformation due to significant Lewis acidity of the Ph₃Ge group (equation 27).

A similar mechanism was proposed for the Ni-assisted intramolecular dehydrogenation of 3-hydroxygermyl acids 132 (R, R’, R”’, R”” = H, Me, Ph), which yields germalactones 133 instead of the anticipated polymeric products (equation 28).⁴⁵⁶,⁴⁵⁷

Reaction of HGeCl₃ with enolizable ketones produces compounds of the type Cl₃GeC(Me)(R)CH₂COR’ 134a and 134b. Their structures were confirmed by X-ray crystallography.⁴⁵⁸

Trichlorogermyl derivative 135 was obtained by passing ketene and acetone vapors through HGeCl₃.⁴⁵⁹

Structures and details of the intramolecular interaction of compounds 128–135 were studied by IR⁴⁴⁷,⁴⁶⁰ and NQR ³⁵Cl⁴⁴⁷,⁴⁶¹–⁴⁶⁴ spectroscopy and by X-ray crystallography whose results are given in Table 31.
In \(\beta\)-trichlorogermyl derivatives of acids 128a–f and ketones 129a, 129b, 134a and 134b containing a hypervalent fragment \(O \rightarrow GeCl_2 \cdots Cl\), the \(O \rightarrow Ge\) bond lengths vary from nearly the sum of the covalent radii of these elements (1.88 Å) to the sum of their van der Waals radii (3.67 Å). Consequently, the environment of the Ge atom changes from distorted tetrahedron with a weak additional \(O \cdots Ge\) interaction (in acids 128a and 128b) to significantly distorted TBP with axial O and Cl atoms (in ester 128c and the four ketones) to slightly distorted TBP (in amides 128d, 128e and imide 128f). In acids 128a and 128b the \(O \cdots Ge\) interaction seems to be of a purely electrostatic nature and

</table>

\(^a\) Deviation of the Ge atom from the equatorial plane toward Cl.

\(^b\) Two independent molecules in the unit cell.

\(^c\) Data for the analogous Br\(_3\)GeCCCO fragment.
there is no coordination with the nearest O···Ge contacts being 4.60 Å (intramolecular) and 4.18 Å (intermolecular)\textsuperscript{471}.

In amides \textbf{128d} and \textbf{128e} the O → Ge distance is the shortest due to a high donor capacity of the amide group. Replacement of the Me group at nitrogen in \textbf{128e} by the acetyl group in imide \textbf{128f} leads to a weakening of the O → Ge interaction\textsuperscript{451}. At the same time the concurrent C=O···H interaction in acids \textbf{128a} and \textbf{128b} weakens the intramolecular O → Ge coordination.

There is a linear relationship between the endocyclic angles OGeC ($\alpha$) and COGe ($\beta$) and the coordination O → Ge bond length (equations 29)\textsuperscript{472}.

\[
\alpha = -20.8 \, d(\text{Ge-O}) + 126.8 \, (r = 0.991, \, n = 7) \quad (29a)
\]
\[
\beta = -18.2 \, d(\text{Ge-O}) + 150.8 \, (r = 0.979, \, n = 6) \quad (29b)
\]

On extrapolation of the equations 29 to a O–Ge distance equal to the covalent bond length (1.75 Å), the environment of pentacoordinate germanium atom corresponds to that of an ideal trigonal bipyramid ($\alpha = 90^\circ$), whereas the valent C–O → Ge angle acquires a value $\beta = 120^\circ$.

As the O → Ge interaction strengthens, a simultaneous weakening of the Ge–Cl\textsubscript{ax} bond and a reduced difference between axial and equatorial Ge–Cl bond lengths takes place (Table 31). The weakening of the O → Ge coordination is accompanied by an increase in the deviation of the germanium atom from the equatorial plane toward the halogen substituent (Scheme 8) and it nearly reaches a value of 0.67 Å for the tetrahedral molecule GeCl\textsubscript{4}\textsuperscript{473}.

\[
\text{SCHEME 8. The deviation } \Delta \text{Ge of the germanium atom from the equatorial plane}
\]

Evaluation of the changes in the O → Ge and Ge–Cl\textsubscript{ax} bond orders by using Pauling’s relation\textsuperscript{474} $\Delta d(n) = d(n) - d(l) = c \ln n$, where $d(l)$ is the ordinary bond length and $d(n)$ denotes the length of the bond of $n$ order, leads to equation 30 for 14 experimental points:

\[
\Delta d(\text{Ge-Cl, Ge-O}) = -0.89 \log(0.50 \pm 0.82\Delta \text{Ge}) \quad (30)
\]

By using a sum of the bond order of 4 in the hypervalent O → GeCCl\textsubscript{2}–Cl fragment and a value of 1 for the axial bonds, values of 0.92 and 0.87, respectively, are obtained for the coefficient $c$. These and the previously calculated value of 0.80 for penta- and hexacoordinate Ge compounds\textsuperscript{475} are lower than $c$ for tin (1.20\textsuperscript{475}). This demonstrates a decreased tendency toward expanding the coordination sphere of germanium atom compared to that of tin\textsuperscript{476}.
The O → Ge bond distances of 2.29–2.39 Å in the steroids 129a and 129b are in the range of 'average' coordination\textsuperscript{177}. The extent of the deviation of the geometry of a hypervalent fragment from the ideal TBP is characterized by the $\Delta \Omega$ value ($\Delta \Omega = 2\pi - \Omega$, where $\Omega$ is the solid angle formed by the directions of the three equatorial bonds around the Ge atom\textsuperscript{478}) of about $91 \pm 1$ deg for the solid angle for both compounds\textsuperscript{450}. This value is intermediate between those for an ideal TBP (0°) and for an ideal tetrahedral coordination (180°).

Quantum-chemical calculations of molecular and electronic structure of trichloroorganogermanes 128d, 128e, 134a and 134b were carried out using AMPAC and HyperChem software\textsuperscript{479}. In the case of amide 128d having one of the shortest O → Ge bond lengths (2.166 Å) in the solid state, only the PM3 method gives reasonable agreement between the theoretical and experimental data for this (ca 2.43 Å) and other distances as well as for valent and torsion angles. The O → Ge bond length increases significantly (up to 2.67 and 2.57 Å) on substitution of the chlorine atoms in 128d with hydrogens or methyl groups while more electronegative fluorine atoms decrease the distance to 2.31 Å.

c. Amide-type (O–Ge) compounds. Hetero-analogs of β-germyl-substituted carbonyl compounds, namely N-germylmethyl derivatives of amides, lactams and imides containing a five-membered GeCNCO chelate ring, were prepared originally by the reaction of trihalogenogermerane ethers with the corresponding N-halogenomethyl compounds (equations 31–34)\textsuperscript{452,480,481}.

$N$-Chloromethyl derivatives of $p$-halobenzyl amide are inactive toward HGeCl$_3$ · 2Et$_2$O. However, under severe conditions they react with HGeCl$_3$ · dioxane to yield the amides (136, $R = F, Cl$)\textsuperscript{480}.

The $\nu$(C=O) absorption band of the $N=\cdot C=\cdot O$ fragment in the IR spectra of compounds 136–140 is shifted significantly (by 60–100 cm$^{-1}$) to a low-frequency region compared with their NH and NCH$_2$Hal derivatives, indicating a rather strong O → Ge coordination\textsuperscript{480}.

\[
p-RC_6H_4CON(R')CH_2Cl \xrightarrow{\text{HGeCl}_3 \cdot 2\text{Et}_2\text{O}} p-RC_6H_4CON(R')CH_2GeCl_3 \quad (136a) \quad R = R' = Me
\]

\[
p-RC_6H_4CON(R')CH_2Cl \xrightarrow{\text{HGeCl}_3 \cdot 2\text{Et}_2\text{O}} p-RC_6H_4CON(R')CH_2GeCl_3 \quad (136a) \quad R = R' = Me
\]

The amide and lactam groups in 136 and 137 are inactive when boiled with concentrated HCl; on reaction with Grignard reagents they yield trialkylgermyl derivatives (equation 35). According to the IR spectra, there is no intramolecular O → Ge interaction in compounds of type 141\textsuperscript{480}.

Germatranes and germocanes were prepared by reaction of the trihalogenogermeranes 136–140 and triethanolamine or diethanolamines (Sections VI.B and VI.C.1.a). In these compounds the Ge atom participates in N → Ge transannular interaction and additional intra- or intermolecular interactions are absent. For example, the shortest O ··· Ge contacts for germatranes $N$(CH$_2$CH$_2$O)$_3$GeCH$_2$CH$_2$COOMe\textsuperscript{482} and
N(CH₂CH₂O)₃GeCH₂CH(Me)COOMe are 4.86 and 4.83 Å, respectively.

\text{PhCONHCH}_2\text{GeCl}_3 & \xrightarrow{\text{MeMgI}} \text{PhCONHCH}_2\text{GeMe}_3 \\
(136) R = R' = \text{H} & (141)
\end{align*}
\]

Reaction of ClCH₂GeMe₂Cl with N- or O-trimethylsilyl amides and lactams yields O → Ge pentacoordinate complexes 142–144.

The multistage mechanism of the reaction was studied by NMR monitoring (Scheme 9, equation 36). A trans-metallation leads to formation of the intermediate Me₂GeCH₂Cl derivative 145, which was identified shortly after the reagents were mixed.
in CDCl$_3$ at $-20^\circ$C. Under these conditions, the reaction is apparently reversible with the equilibrium shifted toward the initial compounds.

At higher temperatures (from $-10$ to $+10^\circ$C) the transmetallation products (145) undergo a gradual conversion to the O-alkylation products (146) by chlorine migration from carbon to germanium. Further increase in temperature (up to $60^\circ$C) results in isomerization to the N-alkylation products (142-144). The latter reaction is similar to Chapman rearrangement, although it occurs under remarkably mild conditions. The half-lives for conversion of imidates (146) ($R, R' = (CH_2)_n, n = 4, 5$) are 13 and 25 min, respectively.$^{488}$

Kinetically controlled imidates (146) may be isolated at $20^\circ$C on a preparative scale in 80% yields. The thermodynamically stable products (142-144) were obtained by heating of the initial reagents or the isolated imidates (146) at $60-100^\circ$C for several hours.

Conversions similar to (145) $\rightarrow$ (146) $\rightarrow$ (142-144) occur with the corresponding Si analogues under much milder conditions. In these cases, not only the trans-silylation products but also the corresponding Si imidates are formed as intermediates, which can only be observed by NMR monitoring.$^{492}$

Pentacoordination of the Ge atom in chlorides (142-144) may be detected from the IR spectra. Similar to the isostructural silicon compounds, the N–C=O fragment in (142-144) shows two characteristic absorption bands at 1500–1750 cm$^{-1}$, an intense band around $1600$ cm$^{-1}$ and a less intense band at ca $1510$ cm$^{-1}$.484

Among other compounds, the first optically active amide derivative (142b) containing an asymmetric carbon and a five-coordinated germanium was obtained by the same method$^{486}$ or by a one-pot synthesis from $N$-[(S)-1-phenylethyl]acetamide, hexamethyldisilazane and ClCH$_2$GeMe$_2$Cl. The latter method does not require the initial preparation of $N$-silylated amide and gives a higher overall yield of the final product.

The thermodynamically controlled reactions between ClCH$_2$GeMe$_2$Cl and O- or N-TMS derivatives of 5-ethyl-3-morpholinone$^{493}$ and 2,5-piperazinedione$^{489}$ yield the monochelate (147) and bis-chelate (148a), respectively.

The chlorine atom in (142b) and (144c) may be replaced with bromine or triflate group to give (149) or (150) by the reaction with the appropriate Me$_3$SiX ($X = Br^{486}, OTf^{489}$) reagent (equation 37). These substitutions proceed under mild conditions, which is a result of a
stronger O → Ge coordination in the reaction products than in initial chlorides. Dichloride 148a was converted into bis-chelate ditriflate product 148b by the same method\(^{489}\).

Treatment of the chloride 142a with 5\% solution of KOH in methanol followed by neutralization with citric acid gave germanol MeC(O)N(Me)CH\(_2\)GeMe\(_2\)OH. In the case of bis-germyl derivative 142d the product of heterocyclization 151 was obtained (equation 38)\(^{485}\).

Reduction of chlorides 142a,c,d with an excess of LiAlH\(_4\) affects two reaction centers and yields the corresponding hydrides EtN(R)CH\(_2\)GeHMe\(_2\) (R = Me, CH\(_2\)CH=CH\(_2\), CH\(_2\)GeHMe\(_2\)). The latter was also isolated by reduction of digermamorpholine 151\(^{485}\).
Reaction of chlorides 142b and 144d with Grignard reagents proceeds with high chemoselectivity at the Ge–Cl bond to give the Ge-alkylated products 152a–c (equation 39). According to the IR spectra, the Ge atom in 152a–c is four-coordinated.

Similarly, 142a reacts with BuLi to yield the alkylation product 152d.

\[
\text{RC(O)NR'CH}_2\text{GeMe}_2\text{Cl} \xrightarrow{R''\text{MgX} = \text{MeMgI, PhCH}_2\text{MgCl}} \text{RCONR'CH}_2\text{GeMe}_2\text{R''} \quad (39)
\]

(a) \( R = \text{Me}, R' = \text{CH(Me)Ph}, R'' = \text{Me} \\
(b) \( R = \text{R'Me}, R' = (\text{CH}_2)_5, R'' = \text{Me} \\
(c) \( R = \text{R'Me}, R' = (\text{CH}_2)_5, R'' = \text{CH}_2\text{Ph} \\
(d) \( R = \text{R'Me}, R'' = \text{Bu}
\]

(142b, 144d) (152)

The relative reactivities of 144d and Me3GeCl as well as of chlorides 142b, 144d and their Si analogues in the Grignard reaction have been determined by a competing reactions method and the results are given in Table 32.

The relative reactivity of 144d to Me3GeCl is significantly higher than in the other cases, probably due to Ge–Cl bond lengthening in the hypervalent O → Ge–Cl fragment of 144d compared with Me3GeCl. The difference in reactivity of the pentacoordinated chlorides of Ge and Si in their reaction with Grignard reagents is almost insignificant. This is a result of lesser relative lengthening of the Ge–Cl than Si–Cl bonds in pentacoordinate derivatives, in comparison with the tetracoordinate model compounds of these elements.

### i. Crystallographic data
Numerous X-ray structures for (O–Ge)-chelate complexes containing the GeCNCO fragment were reported in the literature and reviewed. The main geometrical characteristics of the central coordination sites are collected in Table 33. The major part of these compounds has the OGeC3X hypervalent fragment.

All of the compounds above have a near-TBP geometry, with the donor oxygen atom and an electronegative substituent X occupying the axial positions. The GeX angles are generally in the range of 169–171°. The axial O → Ge and Ge–X bonds are longer than the ‘standard’ values determined in tetrahedral derivatives. Correlations between structural parameters of the compounds with an OGeC3Cl unit and other five- and four-coordinated germanium derivatives were discussed. Some general features of the hypervalent bonding and the influence of the nature of central atom, axial substituent X and the C2O-chelated ligand on the character of intramolecular coordination in these complexes may be concluded from the data in Table 34.

$^f$Two independent molecules in the unit cell.

$^{g}$Ge−Cl$_{eq}$ 2.132, 2.148 and 2.150, 2.141 Å.

$^{h}$Ge−Cl$_{eq}$ 2.125, 2.133 Å.

$^{i}$Reference 499.

In accordance with the rule of the constancy of the total order of the axial bonds in a hypervalent fragment$^{500}$, the shortening of the dative O → Ge distance is accompanied by a corresponding relative lengthening of the Ge−X distance. Thus, the O → Ge bond is longer in 144a (2.341 Å) than in 144c (2.181 Å). Consequently, in 144a the Ge−Cl distance is shorter (2.324 Å) than that in 144c (2.343 Å).

The smallest total relative lengthening of the bonds in a hypervalent fragment O → M−X (which may be calculated as the relative lengthening of the O → M and M−X bonds in comparison with ‘standard’ bond lengths in tetrahedral compounds; Δd, %) are observed for the compounds with minimal deviation of the central atom from the equatorial plane, i.e. for ΔM ≈ 0 (Tables 33 and 34). In the case of germanium, such a compound is the bromide 149 (ΔGe = 0.066 Å, Δd(O−Ge) = 22%, Δd(Ge−Br) = 10%). The higher ΔGe value in chlorides 144a,c,d (0.15−0.19 Å) leads to larger relative bond lengthening (25−32% for Δd(O−Ge) and 8−10% for Δd(Ge−Cl)). The behavior of the analogous silicon compounds is similar. The corresponding bond lengthenings are 30, 18, 9 and 6% for O−Si bonds and 5, 13, 41 and 53% for the Si−Hal bonds in fluoride MeC(O)N(CH(Ph)Me)CH$_2$SiMe$_2$F (153) and in 1-(dimethylhalosilylmethyl)-2-piperidones (Hal = Cl, Br, I, respectively).

According to the criteria proposed on the basis of X-ray structural data,$^{477,486,501}$ the O−Ge distances (2.18–2.35 Å) in monochlorides 142, 144, 147 and 148a fall within the region of ‘average’ coordination distances; the corresponding Ge−Cl bond lengths (2.32−2.36 Å) are larger than ‘standard’ (tetrahedral) distances by only 0.2−0.3 Å. The intramolecular O → Ge coordination in trichlorides 137 and 136d is ‘strong’ (for a
The nature of the axial ligand affects substantially the TBP geometry. In germanium derivatives the $\Delta \Omega$ values decrease by ca 20 and 78° upon substitution of the Cl atom (in 144a–d, 142b is stronger for the larger lactam derivatives or the acyclic compounds (the substituents, where $\Delta \Omega$ being 0.197, 0.192, 0.147, 0.154 and 0.127 Å, respectively). On the contrary, the $\Delta \Omega$ values increase from 0.147 to 0.176 and 0.20 Å, respectively). At the same time, most trichlorides except the amide and the steroid derivatives 128d, 128e, 129a and 129b (Table 31) have a ‘weak’ coordination (2.48–3.23 and 2.13–2.33 Å, respectively). The geometry of the hypervalent OMC$_3$X fragment (M = Ge, Si) may be also characterized by the $\Delta \Omega = 2\pi - \Omega$ parameter, where $\Omega$ is a solid angle formed by equatorial bonds of the central atom. $\Delta \Omega = 2\pi - \Omega$ (0° for ideal TBP and 180° for ideal tetrahedron).

The nature of the axial ligand affects substantially the TBP geometry. In germanium derivatives the $\Delta \Omega$ values decrease by ca 20 and 78° upon substitution of the Cl atom (in 144a–d, 142b is stronger for the larger lactam derivatives or the acyclic compounds (the substituents, where $\Delta \Omega$ being 0.197, 0.192, 0.147, 0.154 and 0.127 Å, respectively). On the contrary, the $\Delta \Omega$ values increase from 0.147 to 0.176 and 0.20 Å, respectively). At the same time, most trichlorides except the amide and the steroid derivatives 128d, 128e, 129a and 129b (Table 31) have a ‘weak’ coordination (2.48–3.23 and 2.13–2.33 Å, respectively). The geometry of the hypervalent OMC$_3$X fragment (M = Ge, Si) may be also characterized by the $\Delta \Omega = 2\pi - \Omega$ parameter, where $\Omega$ is a solid angle formed by equatorial bonds of the central atom. $\Delta \Omega = 2\pi - \Omega$ (0° for ideal TBP and 180° for ideal tetrahedron).
by Br (in 149) and Br by OTf (in 150), respectively. Thus, this parameter changes in the same order with the structural parameter $\Delta Ge$ (the deviation of the germanium from the plane defined by the three equatorial ligands) discussed above. The signs of both $\Delta Ge$ and $\Delta \Omega$ remain the same in the cases of Cl and Br and become negative while the inversion of the configuration of the central atom in the OTf derivative takes place ($\Delta Ge = -0.18$, $\Delta \Omega = -59^\circ$ for 150). In terms of the $S_N2$ reaction coordinate, the structures of 142b and other chlorogermanes with hypervalent OGeC$_3$X fragment (Table 34) represent an early stage of the reaction (Scheme 10, $M = Ge, X = Cl$). Bromide 149 ($X = Br$) is a model of a nearly TBP intermediate state, and triflate 150 ($X = OTf$) represents the final stage with inverted germanium center.

In the case of the silicon derivatives L$^n$SiMe$_2$X and R$^*$SiMe$_2$X ($R^* = MeC(O)N(CH(Ph)Me)CH_2, X = Hal or OTf$) a similar inversion of the TBP configuration takes place upon substitution of Cl by Br (Table 34, Scheme 10). The distortion of the TBP environment is increased in the series of Si, Ge, Sn, especially on replacement of the Si atom by Ge (the $\Delta \Omega$ values for chlorides L$^n$MMe$_2$Cl are 19, 45 and 55°).

Lactamomethyl and amidomethyl derivatives of five-coordinate germanium and silicon, in particular halides 142b, 144b, 149 and their Si analogues, Si-142b, Si-144b and 153, were compared with respect to the relative deviations of the central atoms from the plane of the three equatorial substituents. The relative deviations were defined as $\Delta M_s - \Delta M/\Delta M_s$ (where $\Delta M$ is the deviation of the five-coordinate M atom from the equatorial plane toward the Hal atom and $\Delta M_s$ is the deviation of the tetrahedral M atom from the plane through the three substituents in the model compound) on formally going from the four-coordinate state of the central atom to the five-coordinate state (Table 34). This parameter is suggested to characterize the ability of the four-coordinate Ge or Si atoms to deviate from the equatorial plane when subjected to the attack of the nucleophilic reagent (the O atom of the amide fragment) yielding a five-coordinated intermediate (i.e. geometric rigidity of the Ge or Si substrate) and the donor ability of the oxygen atom in the C,O-chelating ligand with respect to the corresponding electrophilic center. The deviation of the M atom from the plane of three carbon atoms in the Me$_3$MHal molecules calculated from the geometry of Me$_3$MHal optimized by the AM1 method was used as the standard value of $\Delta M_s$.

The values of the relative displacements of Ge and Si atoms in structural analogues (Table 34) indicate a higher geometric rigidity of the Ge atom environment and higher
donor ability of the O atoms in amides 142b and Si-142b compared to those in five-membered lactams 144b and Si-144b.

Electroconductivity of the pentacoordinated germanium compounds is lower than that of their Si analogues496. Nevertheless, the relatively high electroconductivity of triflate 150 indicates the possibility of a dissociative mechanism for reactions of pentacoordinated germanium compounds with relatively good leaving groups at the Ge atom which give cations with tetracoordinated germanium atom.

**ii. Dynamic 1H NMR spectroscopy.** In halides 142b, 144b and 149, the presence of a chiral carbon atom makes the methyl groups on Ge diastereotopic. The coalescence of their signals with a change in temperature was used to obtain ligand exchange barriers resulting from either pseudorotation, or O—Ge cleavage followed by rotation and reclosure, or intermolecular exchange (Table 35). Apparently, a process involving inversion of germanium (Berry-type pseudorotation) which take into account the low conductivity of chloride 144c (in CD2Cl2) can be suggested only for chlorides 142b and 144b in CDCl3 in the absence of added external nucleophiles. However, a noticeable decrease in the ΔG‡ value on going from chloride 142b to chloride 144b, as well as from Si-142b to Si-144b, i.e. on a change to compounds with a weaker O→M (M= Ge, Si) coordination bond, allows one to assume O—M cleavage as a most likely stage of the process. This stage can be also considered as probable when addition of a stoichiometric quantity of external nucleophiles resulted in lowering of the barrier.

The nature of the electronegative substituent at the central atom substantially affects the barrier for ligand exchange at both germanium and silicon. Thus, the replacement of Cl by Br on going from chloride 142b to bromide 149 decreases ΔG‡ (for example, to 17.8 kcal mol−1 in CDCl3). However, the effect of a change of the halogen atom in CD3OD (a solvent possessing higher solvating ability) is virtually absent. Thus, for bromide 149, ΔG‡ = 15.3 kcal mol−1, which is only 0.3 kcal mol−1 lower than that for chloride 142b.

A decrease in the barrier for ligand exchange on going from the germanium derivatives to the corresponding silicon ones when all other factors remain the same (Table 35) is indicative of the higher configurational stability of the five-coordinate Ge halides under

d(10.8)507.
consideration compared to their Si analogues. This is in agreement with X-ray diffraction data on the higher rigidity of the central OGeC3Hal compared with the OSiC3Hal coordination unit discussed above.

The stereochemical flexibility of chloride 144d and its Sn analogue, Sn-144d, was studied by NMR spectroscopy. The protons of the NCH2M and MMe2 groups (M = Ge, Sn) were anisochronic at < −70°C. The values of activation free energy of the process resulting in chemical equivalence of the protons indicated were determined by the 1H DNMR method in 1 : 1 CDCl3 : C2D2Cl2 and were 9.4 kcal mol−1 (NCH2Ge) for chloride 144d, 9.6 (NCH2Sn) and 9.3 (SnMe2) kcal mol−1 for chloride Sn-144d. The signal anisochronicity was due to the restricted inversion of the seven-membered lactam ring.

2. Derivatives with other bidentate chelating ligands

Although the hypervalency of organogermanium compounds with monoanionic C,O-chelating ligands was the most extensively studied, complexes containing other monoanionic bidentate X,D-chelating ligands (X, D = C, N, O, S) have also been reported. Among them, the first representative triorganogermanium halides with C,N-chelating ligands is 154, whose solid state structure was unambiguously determined by an X-ray diffraction in 1981, as well as lactim ether 155 and the thiolactim ethers, 156a and 156b. The Ge atom in 154 is pentacoordinated due to intramolecular N → Ge coordination and it has a distorted TBP arrangement at the germanium center, with three equatorial carbon atoms and axial chlorine and nitrogen. The axial bond lengths (Table 36) are significantly longer than the sum of the covalent radii for these elements (Table 1).

The synthesis of 155 at the second stage of the reaction between ClCH2GeMe2Cl and the corresponding N-TMS lactam was described above (Scheme 9). The use of N-TMS thiolactam in this reaction leads to isolated 155, unlike 155, as the S-alkylated product. Thiolactim ether 156b was isolated as a by-product in the reaction of (ClCH2)2GeCl2 and N-TMS hexahydro-2-azepinthione (Section X.B).

X-ray determinations reveal for imidates 155 and 156a a TBP structure, with axial nitrogen and chlorine. The Ge–Cl bond is longer in the N–Ge chelate 155 than in the O–Ge chelate 144d (2.460 and 2.354 Å, respectively). In conformity with the constancy of the sum of the order of axial bonds at a TBP atom, it means that the N → Sn coordination is stronger than the O → Ge coordination. This is confirmed by comparison of the distortion degree of the TBP structure of the Ge atom in 155 and 144d.

\( a \)PhN = 2-[(dimethylamino)methyl]phenyl.

\( b \)Deviation of the central atom (Ge) from the equatorial plane; positive \( \Delta \) indicates deviation toward Cl.

\( c \)Two independent molecules.

\( d \)Data for the silicon analogue of 156a are given for comparison.

former, the Ge atom is essentially in the equatorial plane, whereas in the latter it is noticeably shifted from this plane toward the chlorine atom (\( \Delta Ge = 0.15 \) Å)\textsuperscript{491,487}.

The \( N \rightarrow Ge \) (2.054 Å) and Ge−Cl (2.566 Å) distances in thiolactim ether 156a are the shortest and the longest, respectively, among the values known for pentacoordinated germanium derivatives. Moreover, the Ge atom is displaced from the equatorial plane toward the N atom (\( \Delta Ge = −0.05 \) Å) i.e. the Ge−Cl bond represents an ‘additional’ bond.

Comparison of structural characteristics of the thiolactim ethers 156a and the Si analogue, Si-156a (Table 36), shows that the strength of the intramolecular \( N \rightarrow M \) (\( M = Si, Ge \)) interaction is approximately the same in the coordinative \( N \rightarrow MC_3 \)−Cl units. The relative lengthening of the N−M bond in these compounds relative to the normal bond length in the corresponding tetrahedral compounds, as well as \( \Delta Si, \Delta Ge \) and the N−M bond order is actually equal\textsuperscript{496}.

A numerous series of compounds containing a N,O-chelating ligand, namely the derivatives of anthranilic (157) and 3-amino-2-thiophenecarboxylic (158 and 159) acids, were prepared by the reactions of organohalogenermes with esters, amides or lithium derivatives of acids\textsuperscript{510−516}.

An intramolecular O → Ge coordination in the products is suggested on the basis of their IR spectra.

Reaction between 3-amino-2-thiophenecarboxylic acid and \( R_2GeCl_2 \) with a deficiency of the LiNH\(_2\) gives the monoamino compounds 158 while an excess of lithium amide leads to formation of the diamino derivatives 159\textsuperscript{513,515,516}. The authors suggest that intermolecular \( O \rightarrow Ge \) coordination increases the lability of chlorine substituent in the intermediate 158 and favors the formation of the diamino derivatives 159\textsuperscript{510,513,515}.

Reaction of halides 157a and 157c with \( t-\text{BuLi} \textsuperscript{511} \) or of chloride 158a with lithium\textsuperscript{515} leads respectively to germaimines 160a, 160b and 161 stabilized by \( O \rightarrow Ge \) coordination. The dimethylamino derivative 157b was prepared from the fluoride 157a and LiNMe\(_2\) at −40°C in THF while the formation of germaimine 160a requires more drastic conditions\textsuperscript{511}.

In the presence of reagents with labile hydrogen in the germaimines 160 and 161 undergo addition reactions and yield different known and new compounds of the types of 157 and 158, respectively\textsuperscript{512}.

Trifluoroacetoxygermane 162 obtained by the reaction of Ph\(_4\)Ge with CF\(_3\)COOH is a rare example of a pentacoordinated germanium compound where intramolecular coordination leads to formation of four-membered chelate ring\textsuperscript{517,518}. In solution, a O → Ge coordination in 162 was deduced on the basis of the IR spectrum. The \( \nu(C=O) \) absorption band (1745 cm\(^{-1}\)) is about 80 cm\(^{-1}\) lower than that in CF\(_3\)COOH. According to X-ray
The molecules of 162 are monomeric in the crystal. The environment of the Ge atom is a highly distorted tetrahedron with a weak (3.09 Å) additional O···Ge contact. The latter is only by 0.5 Å shorter than the sum of van der Waals radii of the O and Ge atoms (Table 1).

A series of new triphenylgermanium complexes of the type 163 (R = Me, Et, Ph and p-ClC₆H₄) was recently synthesized by the interaction of Ph₃GeCl with the sodium salt of sterically congested heterocyclic β-diketones. In view of their monomeric nature and the bidentate nature of the ligands, which are the conjugate bases of the corresponding

\(\beta\)-diketones, a pentacoordinate structure of these complexes was proposed in which the central germanium atom acquires the TBP geometry.

Halides \(\text{XMe}_2\text{Ge(DMTC)}\) 164a–c provide an example of distorted TBP germanium compounds with the anisobidentate dimethylidithiocarbamate (DMTC) ligand\(^{521,522}\). The latter is significantly asymmetric with a shorter Ge–S\(_{eq}\) bond and a longer Ge–S\(_{ax}\) distance (Table 37). The axial Ge–Hal bonds are considerably longer than those typically found for four-coordinate germanium halides. The Ge–S\(_{ax}\) bond lengths decrease along the series chloride, bromide, iodide, being 2.896, 2.828 (mean) and 2.685 Å, respectively, with a parallel increase in the SGeS bite angle.

The Ge(II) derivative \(165\) reacts with elemental S and Se to give the corresponding thione \(166a\) and selenone \(166b\) at room temperature but the dihydropyridinato compounds

\begin{align*}
\text{(167) (a) } X &= \text{S} \\
\text{(b) } X &= \text{Se}
\end{align*}

An X-ray determination reveals for 167a a distorted TBP structure, with the two N atoms at the axial positions and the two C and S atoms at the equatorial sites.

A novel type of pentacoordinate germanium compound 168 was recently obtained by the reaction of \textit{t}-BuGeCl\textsubscript{3} with mercaptaoacetic acid\textsuperscript{524}. It is likely that \textit{t}-BuGe(SCH\textsubscript{2}CO\textsubscript{2}H)\textsubscript{3} (169) is first formed. Subsequently, an intramolecular nucleophilic substitution takes place on germanium, where one of the \textendash\text{SCH\textsubscript{2}CO\textsubscript{2}H} moieties of 169 acts as nucleophile while the other is the leaving group to give 168.

As shown by X-ray crystallography, the germanium atom in 168 is pentacoordinate with a near-TBP structure. The two Ge\textendash S and Ge\textendash C bonds are equatorial while the two Ge\textendash O bonds are apical at an angle of 166.7° with equal length (\textit{ca} 2.04 Å), which is somewhat longer than the standard Ge\textendash O bond length (\textit{ca} 1.7\textendash 1.8 Å).

16. Hypervalent compounds of organic germanium, tin and lead derivatives

Based on the $^1$H and $^{13}$C NMR spectra which exhibited only one signal each for the CH$_2$ protons and the carbonyl carbons in 168, a rapid equilibrium between two identical pentacoordinate species is proposed in solution (equation 41)$^{524}$.

**B. Bicyclic Complexes. Germocanes and their Analogues**

Bicyclic derivatives of germanium, tin and lead of the type XYM(ZCH$_2$CH$_2$)$_2$D 170 belong to the class of metallocanes. The presence of 1,5-transannular interaction between the D and M atoms in these compounds increases the coordination number of M. Depending on nature of the M atom and the ligands, the molecules of metallocanes may adopt one of the two basic configurations 170A and 170B both in the solid state and in solution. In addition to conformational and molecular dynamic studies, these compounds were also used by Dräger and coworkers for the development of a new concept of the hypervalent bonding for main group elements$^{525}$.

![Diagram of 170A and 170B]

The most common types of germocanes are 1-aza-4,6-dioxagermocanes 171$^{444,526}$ and 172$^{527}$, 1-oxa- and 1-thia-4,6-dithiagermocanes 173 and 174$^{528}$, and 1-aza-4,6-dicarbagermocanes 175–177$^{525}$.

![Structures of 171, 172, 173, 174, 175, 176, 177]

1-Azagermocanes 171 ($X = Y = Me$, Et, R = Me, n-Pr; $X = Y = 2$-Thi, R = Me (171a)) were prepared with good yields from dialkoxygermanes and dialkanolamines$^{444,526}$ (equation 42).

$\text{XYGe(OR')}_2 + (\text{HOCH}_2\text{CH}_2)_2\text{NR} \rightarrow \text{XYGe(OCH}_2\text{CH}_2)_2\text{NR} + 2\text{R'}\text{OH}$ (42) 

Synthesis of the dihydroxy derivatives 172a,b ($X = Y = OH$, R = H (a), Me (b)) was also reported$^{529}$. A new synthetic approach to 1-azagermocanes 171 ($X = Y = 2$-Thi,
R = t-Bu) and 171a, i.e. an exothermic dehydrocondensation of di(2-thienyl)germane and diethanolamines without a catalyst, was reported recently\(^{526}\) (equation 43).

\[
(2\text{-Thi})_2\text{GeH}_2 + (\text{HOCH}_2\text{CH}_2)_2\text{NR} \rightarrow (2\text{-Thi})_2\text{Ge(OCH}_2\text{CH}_2)_2\text{NR} + 2\text{H}_2
\]

\(R = \text{Me, t-Bu}\) (171), (171a) \(\quad (43)\)

1-Oxa- and 1-thiagermocanes 173 and 174 were prepared by refluxing the reagents in equation 44 in benzene until the complete removal of HCl\(^{528}\).

\[
\text{GeCl}_4 + (\text{HSCH}_2\text{CH}_2)_2\text{D} \rightarrow \text{Cl}_2\text{Ge(SCH}_2\text{CH}_2)_2\text{D} + 2\text{HCl}
\]

\(D = \text{O, S}\) (173), (174) \(\quad (44)\)

Reaction of the Grignard reagent \(\text{RN}[(\text{CH}_2)_3\text{MgCl}]_2\) with \(\text{GeCl}_4\)^\(^{530,531}\) or \(\text{PhGeCl}_3\)^\(^{525}\) gives carbagermocanes 175, 176 and 177, respectively, with low yields (3–15\%) (equation 45).

\[
\text{GeCl}_4 + \text{RN}[(\text{CH}_2)_3\text{MgCl}]_2 \rightarrow \text{Cl}_2\text{Ge(CH}_2\text{CH}_2\text{CH}_2)_2\text{NR}
\]

\(R = \text{Me, CH}_2\text{Ph, i-Bu}\) (175–177) \(\quad (45)\)

The yield of 1-thiacarbagermocane \(\text{Cl}_2\text{Ge(CH}_2\text{)}_3\text{S}\) prepared by a similar method is also low (12\%) while its o-analogue \(\text{Cl}_2\text{Ge(CH}_2\text{)}_3\text{O}\) could not be isolated\(^{531}\). Both chlorine atoms in dichloride 175 may be substituted with \(\text{Ph}_3\text{SiO}\) groups by the reaction of 175 with \(\text{Ph}_3\text{SiONa}\) in toluene\(^{531}\).

A different type of germocanes are the spirogermocanes 178, that are prepared by the reaction of polygermaniumsesquioxide \((\text{HOOCCH}_2\text{CH}_2\text{GeO}_{1.5})_n\) with triethanolamine or N-substituted diethanolamines\(^{444,532}\).

![Diagram](image-url)

Similar derivatives of ethylene glycol 179\(^{533}\) and 2-hydroxy-2,2-diphenylacetic acid 180\(^{534}\) were also reported. The former was formed in the reaction of \(N\)-methyl diethanolamine and \(\text{GeO}_2\) or \((n\text{-PrO})_4\text{Ge}\) in the presence of ethylene glycol\(^{533}\).

Spiroyclic ‘double germocanes’ 181 and 182 were prepared by the ligand exchange reactions from dihydroxygermocanes 172a and 172b and the derivatives of dithiols \((\text{HSCH}_2\text{CH}_2)_2\text{D}\) \((D = \text{O, S})\) in boiling methanol\(^{527}\).

Recently, the molecular structures of several germocanes and spirogermocanes were determined. Tables 38 and 39 provide selected structural parameters of the TBP structures.

¹Deviation of the Ge atom from the equatorial plane toward the X substituent.

including bond lengths of germanium to the two apical ligands, the D–Ge–X angles and the displacement (Δ) of the Ge atom from the central plane defined by the three equatorial ligands.

The Ge atoms in the germocanes (Table 38) are pentacoordinated due to hypervalent D → Ge–X interaction. The coordination environments of these atoms are distorted TBP with the donor D (D = N, O, S) and the X in axial positions. The intramolecular coordination D → Ge bond belongs to both 5-membered heterocycles.

The D → Ge–X angles in all structures fall in the range of 173–178°, with the only exception of the 2-thienyl derivative 171a. The distortion of the TBP configuration in the latter compound is the most prominent. Despite the significant increase of the O–Ge–O angle, the oxygen atoms still occupy equatorial positions while the nitrogen atom is axial, which is also the case in its Si analogue Ph₂Si(OCH₂CH₂)₂NH. This contrasts with the structure of the Sn analogue (t-Bu)₂Sn(OCH₂CH₂)₂NMe (see below) where the oxygen atoms occupy axial positions.

The Ge atom in germocanes is shifted from the equatorial plane toward the X substituent. Both axial bonds are elongated as predicted by the concept of the 3c–4e hypervalent bond. The D → Ge distance is larger than the sum of covalent radii of these elements but is still significantly shorter than the sum of their van der Waals radii (Table 1).

At present, a detailed discussion of the influence of different factors on the strength of intramolecular coordination in germocanes is lacking due to insufficient experimental data. However, there is a tendency of weakening the coordination upon replacement of chlorine substituent at the Ge atom with a less electronegative 2-thienyl group as well as by the replacement of a donor nitrogen atom by oxygen and further with sulfur.

The ΔGe values in the spirocyclic derivatives (Table 39) are smaller than those in regular germocanes. Thus the TBP coordination polyhedra of the Ge atoms in the former are less distorted. The N → Ge distances in spirocyclic germocanes are also smaller, which indicate a stronger coordination in these compounds.

Both spirocyclic ‘double germocanes’ 181 and 182 have distorted tetrahedral geometry of the central atom. Four chalcogen atoms occupy a pseudo-equatorial plane. The

¹Deviation of the Ge atom from the equatorial plane toward X.
distortion may be attributed to the formation of two eight-membered chelating rings and probably to weak interactions between the Ge and free O or S atoms of the ligands (the Ge―O distances in 181 are 2.915 and 2.955 Å; the Ge―S distances in 182 are 3.236 and 3.453 Å).

In the case of 178b, when the nitrogen atom is substituted by \( R = CH_2CH_2OH \), the spirocyclic structure remains intact in water, but in aprotic solvents the compound is present in the tautomeric equilibrium germocane-germatrane (equation 46)\(^{538,542,543}\). Both forms exist in DMSO solution at room temperature and at higher temperatures the equilibrium shifts toward the germatrane\(^{538}\) (see Section VI.C).

Organogermocane-3,7-diones \( R^1R^2Ge(OCOCH_2)_2NCH_3 \) [\( R^1, R^2 = Me_2, Ph_2, (OSiMe_2CH_2) \)] have been prepared from the corresponding organogermanes and MeN(\( CH_2COOH \))\(^{2544}\). For 183, \( R^1 = R^2 = Me \) both NCH\(_2\) protons and R groups are nonequivalent on the NMR time scale. At higher temperatures in DMSO-\( d_6 \) a coalescence of both resonances is observed with an activation barrier for the enantiomerization (equation 47) of \( \Delta G^\neq = 19.1 \) kcal mol\(^{-1}\). For a similar tin derivative (\( R^1 = R^2 = t\)-Bu) \( \Delta G^\neq = 20.9 \) kcal mol\(^{-1}\)\(^{1544}\).

The dipeptide derivatives, Me\(_2\)GeGlyGly (184)\(^{546}\) and Me\(_2\)GeGlyMet (185)\(^{547}\), are examples of pentacoordinated germanium compounds with dianionic N,N,O-chelate ligands. X-ray determinations reveal that the polyhedron around Ge in both 184 and 185 is a distorted TBP with the peptide nitrogen and two Me groups in equatorial positions and an oxygen of the unidentate carboxylate group and the amino nitrogen in the apical positions. The axial bond angles are 161.4° and 161.8°, respectively and the tridentate dipeptide ligands have a nearly planar skeleton. The N\(_{eq}\)―Ge distances are shorter than the N\(_{ax}\)―Ge ones (1.888 and 1.889 Å against 2.110 and 2.103 Å, in 184 and 185, respectively). However, the latter distances are shorter than those found for organogermatranes (2.19 to 2.24; Section VI.C.1.b) which, like 184 and 185, contain pentacoordinated Ge but tertiary and not a primary N(amino) as a donor atom.

Short intermolecular N⋯O distances in 185, 2.851 and 2.875 Å, indicate the presence of hydrogen bonds. In contrast, in 184 no intermolecular interactions via a hydrogen bond exist.

A number of dibutylgermanium complexes 186 containing a dianionic N,O,S-chelating ligand was recently synthesized by the reaction of the sodium salt of the corresponding
C. Tricyclic Complexes

Discovery of silatranes in 1961 and their amazing biological activity initiated active investigations of the analogous derivatives of other group 14 elements. The first germatranes and stannatranes were prepared in 1965 and 1967–1968, respectively. The most distinctive features of the atranes and their tricyclic analogues with tripodal fragments of triethanolamine and its carba- and hetero-substituted derivatives are the unusual cage structure with near-TBP environment of the central atom, with intramolecular interaction of the latter with the heteroatom. Recently, the germatranes are the most studied derivatives of hypervalent germanium with N→Ge coordination.

1. Germatranes and their C-organo-substituted derivatives

a. Synthesis and reactivities. The most common examples of germatranes and their C-organo-substituted (usually 3,7,10-trimethyl) analogues are compounds 187–195.

These compounds can be prepared either by formation of the atrane framework at the central atom or by substitution reactions of other atranes. The most common method of the atrane fragment formation is trans-alkoxylation reactions that proceed under moderately mild conditions (equation 48). In this way the following derivatives 188–191 were prepared: X=OMe, OEt, OP, OP-t, Cl, Br, Me, Et (188a), t-Bu (188b), and other alkyls, 1-Ad, CPh3, Vin, All (188c), CH=CH-Ph (188d), CH2SiMe3, CH2Cl (188e), CH2I (188f), CH2CONHAlk, CH(Me)N(CH2)3C=O (188g), CH2NHC6H4Cl-p (188h) and other amidomethyl and imidomethyl groups, CH2CH2OMe,
CH₂CH₂COOMe (188i) , CH₂CHMeCOOMe (188j) , CH₂CH₂CONH₂ (188k) , CH₂CH₂CN, Ph (189a) , o-, m- and p-Tol (189b–d) , 1-Naphthyl (189e) , 2- and 3-Fu, 2-(5-COOC₂H)₃ (189g) , 3-Thi (189h) and others; R′ = Me, Et, Pr, i-Pr.

\[
X-\text{Ge(OR′)}_3 + (\text{HOCH}_2\text{CH}_2)_3\text{N} \longrightarrow X-\text{Ge(OCH}_2\text{CH}_2)_3\text{N} + R′\text{OH}
\]  

(48)

In contrast to silatranes, the reaction in equation 48 proceeds without a base (NaOH, KOH) catalyst. For example, 1-trifluoromethylgermatrane (196) and 1-isothiocyanatogermatrane (197) were prepared from triethanolamine (TEAA) and CF₃Ge(OEt)₃ or SCNGe(OEt)₃ at room temperature in THF or CH₂Cl₂, respectively. 6-(Gerimatranylethyl)-substituted β-carbolyne and E-β-styrylgermatrane were prepared recently by a GeBr₂ insertion into the C–Br bond of β-bromostyrene, subsequent alcoholysis of the tribromide to triethoxygermyl derivative and re-etherification of the latter with TEAA.

1-(1-Trimethylsilylcyclopropyl)germatrane, the first example of cyclopropylgermatranes, was prepared by cyclopropanation of 1-trimethylsilyl-1-trimethoxygermylethylene with CH₂I₂ in the presence of a Zn-Cu catalyst and subsequent re-alkoxylation with TEAA.

The applicability of the method is limited by the instability (including hydrolytic) of some initial alkoxygermanes. However, hydrogermatranes may be prepared from stable TEAA or alcohol complexes of trialkoxygermanes that do not exist in the uncomplexed form.

Reaction of tetraalkoxygermanes with large excess of TEAA gives N[CH₂CH₂OGe(OCH₂CH₂)_3N]₃ with the three germatrane fragments. Subsequent hydrolysis leads to 1-hydroxygermatrane. However, better yields of 190a as well as its 4-ethyl (198) and 3,7,10-trimethyl (194a) derivatives may be achieved by exothermic reaction of GeO₂ with TEAA or 2-hydroxybutyl-bis(2-hydroxyethyl)amine in the presence of a catalytic amount of water.

The products of partial hydrolysis of organyltrichlorogermanes, i.e. polyorganogermesquioxanes, react with TEAA under more drastic conditions (refluxing xylene/KOH) and are suitable for synthesis of the 1-organylgermatranes with thermally and hydrolytically stable Ge–C bonds (equation 49).

\[
1/n(R-\text{GeO}_{1.5})_n + (\text{HOCH}_2\text{CH}_2)_3\text{N} \longrightarrow R-\text{Ge(OCH}_2\text{CH}_2)_3\text{N} + \text{H}_2\text{O}
\]  

(49)

This reaction was recently used for the preparation of new types of germatranes (R = CHR′CHR′CONHCH₂COOEt; R′, R′ = H, Me) containing α-amino acid fragments.

A less common method of atrane fragment formation is based on amino derivatives. Reaction of (Me₂N)₃SiCH₂Ge(NMe₂)₃ with TEAA in the presence of methanol leads to 1-(1-silatranymethyl)germatrane.

Tetrahalogermanes and organotrihalogermanes are more readily available reagents than the corresponding alkoxy and amino derivatives. However, their direct reactions with TEAA are almost unknown. A rare exception is the synthesis of the CF₃-germatrane from TEAA and CF₃GeCl₃; the by-product HCl forms an adduct with TEAA. In contrast, metallated (Na, SnR₃) and organoelement (B, SiMe₃) derivatives of trialkanolamines are widely used (e.g. equation 50).

\[
X-\text{GeHal}_3 + (\text{Alk}_3\text{MOCH}_2\text{CH}_2)_3\text{N} \longrightarrow X-\text{Ge(OCH}_2\text{CH}_2)_3\text{N} + \text{Alk}_3\text{MHal}
\]  

(50)

X = Hal, Alk, Ar; M = Si, Sn
16. Hypervalent compounds of organic germanium, tin and lead derivatives

Esters of α-germatranylcarboxylic acids $R''\text{OOCR}'\text{Ge(OCH}_2\text{CH}_2)_3\text{N}$ (199) ($R = H, \text{Me}; R' = \text{Me, Ph, COOEt, SiMe}_3$) and their 3,7,10-trimethyl-substituted analogues (200) were prepared recently by using organotin derivatives of trialkanolamines from the corresponding organotrichloro- and tribromogermanes$^{576}$. The structures of compounds 199a ($R = H, R' = \text{Ph, R''} = \text{Me}$), 199b ($R = H, R' = \text{SiMe}_3, R'' = \text{Me}$) and 199c ($R = R' = R'' = \text{Me}$) were determined by X-ray diffraction. By the same method 1-(phenylalkynyl)germatrane (201) was synthesized from $\text{Cl}_3\text{GeC≡CPh}$ while the corresponding organotribromogermanes served as precursors to 1-allylgermatrane (188c)$^{578}$ and its 3,7,10-trimethyl analogue$^{579}$, 1-diphenylmethyl-, 1-(phenyl)(trimethylsilyl)methyl- and 1-(1-indenyl)germatranes$^{572}$, 1-(9-fluorenyl)germatrane (202)$^{577}$ and its 9-Me$_3$Si (203a) and Me$_3$Ge (203b) derivatives$^{580}$, 1-(9-fluorenyl)-3,7,10-trimethylgermatrane (204), its 9-Me$_3$Si (205a) and 9-Me$_3$Ge (205b) derivatives$^{581}$.

The organotin method was also used for preparation of 1-hydrogermatrane 187 from the trichlorogermane complex with ether$^{572}$. A reductive dehydrochlorination with in situ generated trisodium salt of TEAA was used for the synthesis of carbofunctional germatranes (equation 51)$^{582}$.

$$\text{RCH}_2\text{CHR}'\text{GeCl}_3 + (\text{HOCH}_2\text{CH}_2)_3\text{N} + \text{NaH} \rightarrow \text{RCH}_2\text{CHR}'\text{Ge(OCH}_2\text{CH}_2)_3\text{N}$$ (51)

A series of 2-germatranylmethyl-N-arylsuccinimides 206 was obtained by the addition of trichlorogermane to the corresponding 2-methylenesuccinimides and subsequent reaction with TEAA$^{583}$. The structure of 2-germatranylmethyl-N-p-tolylsuccinimide 206a was confirmed by X-ray crystallography$^{584}$.

Boratrane was used as initial compound in one of the most effective syntheses of 1-ethoxygermatrane (190b)$^{585}$. Another type of reaction that lead to new germatranes but retains the original atrane framework was studied with hydrogermatrane 187, alkoxygermatranes 190 and especially 1-hydroxygermatrane (190a)$^{555}$, 586, 587. Reaction of 190a or 194a with amides of silicon, germanium and tin$^{557,555}$ and hydrides of silicon and germanium$^{588,589}$ leads to cleavage of the M–N or M–H bond in the precursors and gives the corresponding organoelement derivatives, in particular siloxygermatranes (2-Thi)$_n\text{Me}_3\text{SiOGe(OCH}_2\text{CH}_2)_3\text{N}$ ($n = 0$ (207a), 1 (207b), 2 (207c), 3 (207d))$^{588,589}$, 1-triphenylsiloxygermatrane (208)$^{588}$ and 1-TMSO-3,7,10-trimethylgermatrane (209). The same compounds may be prepared with lower yields from the reaction of 190a with triorganohalides of silicon, germanium and tin in the presence of Et$_3$N$^{557}$.

Reaktion of 1-methoxygermatrane (190c) with acetic acid in the presence of acetic anhydride leads to 1-acetoxygermatrane with nearly quantitative yield$^{554}$.

Triflates 210 with (a) $R = H$ and (b) $R = \text{Me}$ were prepared recently according to equation 52$^{590}$.

$$\text{Me}_3\text{SiOGe(OCH}_2\text{CHR})_3\text{N} + \text{Me}_3\text{SiOTf} \rightarrow \text{TfOGe(OCH}_2\text{CHR})_3\text{N} + (\text{Me}_3\text{Si})_2\text{O}$$ (210) (52)

The first germatran with amino substituent at the Ge atom, 211a, was synthesized from the hydroxygermatrane 190a according to equation 53. The authors suggest that
(Me₃Si)₂NSnO-germatrane is formed as an intermediate⁵⁹¹.

\[
\text{HOGe(OCH₂CH₂)₃N + Me₃SiOTf} \xrightarrow{\text{Sn[N(SiMe₃)₂]₂}} (\text{Me₃Si})₂N\text{Ge(OCH₂CH₂)₃N}
\]

(190a) \hspace{1cm} (211a) \hspace{1cm} (53)

Halogenating reagents (HF, SOCl₂, Et₃SiBr, Me₃SiI) lead to cleavage of the exocyclic O−Ge bond in alkoxy- and TMSO-germatranes 190b, 207a and 209 and form the corresponding halogermatranes 191 and 195⁵⁵⁷,⁵⁸⁷. In general, the Hal−Ge bond in the latter compounds is rather inert. However, reactions of bromides 191c and 195a with triorganoalkoxystannanes gives the corresponding alkoxides 190 and 194, including (−)-1-menthoxygermatrane 190d, with high yields⁵⁹²,⁵⁸⁷.

Recently, it was shown that the atrane fragment in germatranes is sometimes stable toward organolithium reagents⁵⁹⁰. For example, aminogermatrane 211a and its 3,7,10-trimethylamino analogue 211b may be prepared from the reaction of LiN(SiMe₃)₂ with bromides 191c and 195c, triflates 210a and 210b, and TMSO derivatives 207a and 209. Systematic study of the reactions of these atranes with cyclopentadienyl-, indenyl- and fluorenyllithium allowed one to determine the optimal reaction conditions. The most versatile substrates for the synthesis of indenyl and fluorenyl derivatives are siloxygermatranes 207a and 209. However, an excess of the more nucleophilic BuLi, t-BuLi or LiNMe₂ reagents leads to cleavage of both SiO−Ge and endocyclic O−Ge bonds and to formation of the corresponding alkyl- or amidogermanes (in particular, Bu₄Ge and (Me₂N)₄Ge). The exocyclic O−Ge bond seems to be the primary target of nucleophilic attack of organolithium reagents, so that the reaction of 207a with one equivalent of t-BuLi gives 1-t-butylgermatrane (188b).

Reaction of 1-allylgermatrane (188c) with polyhalo- and halo-alkanes (BrCCl₃, CCl₄, PrI) under UV irradiation leads to halogermatranes 191⁵⁵⁵ while the CH₂N₂/Pd(OAc)₂ system efficiently gives cyclopropanation products⁵⁷⁸. Addition of Br₂ to (phenylalkyl)germatrane 201 also retains both the atrane fragment and the Ge−C bond and leads to the dibromide PhCBr=CBrGe(OCH₂CH₂)₃N (212)⁵⁷². This is a rare example of a near-quantitative formation of a cis-dibromide (as determined by X-ray data) on Br₂ addition to acetylenes.

A number of new C-functionalized germatranes was reported. The reaction of alkynylgermatrane 201 with two equivalents of N-bromosuccinimide and subsequent hydrolysis lead to α-germatranylketone PhCOCBr₂Ge(OCH₂CH₂)₃N⁵⁷². Metalation of fluorenylgermatranes 202 and 204 proceeds smoothly and gives the corresponding 9-trimethylstannyl derivatives 203c and 205c⁵⁸⁰,⁵⁸¹.

1-(2-Furyl)germatrane can be quantitatively converted into 1-dichloromethylgermatrane (213) by irradiation in CHCl₃ solution⁵⁹³. Ethylgermatrane 187a and CH₃I form the quaternary salt EtGe(OCH₂CH₂)₃NMe⁺I⁻⁵⁵⁴.

The atrane fragment is also retained in the reaction of di-n-butyltin oxide and germatranyl-substituted propionic acids in a 1 : 2 molar ratio which leads to new di-n-butyltin dipropionates n-Bu₂Sn[OOCCH₂CHRGe(OCH₂CH₂)₃N]₂·H₂O (214) (R = H, Me, Ar)⁵⁹⁴. The structure of compound 214a (R = p-ClC₆H₄) was confirmed by X-ray diffraction.

Reactions that affect the atrane fragment are relatively rare. Among the products of hydrogermatrane 187 with Br₂, CH₃I or CH₂I₂, trihalo derivatives of TEAA were detected. Similar results were reported for the reaction of 1-allylgermatrane with I₂⁵⁵⁷.

b. Structure and physical properties. Recently the structures of about 50 germatranes and their C-substituted analogues have been reported. The Ge atom is pentacoordinated due
to hypervalent N → Ge–X interaction. The coordination polyhedron of the germanium is a distorted TBP with nitrogen and ligand X in axial positions. Intramolecular N → Ge coordination is the common bond for three condensed five-membered heterocycles. The Ge atom is shifted from the equatorial plane toward the X substituent. Similar to silatranes, both axial bonds in germatranes are weakened due to the presence of a three-center four-electron hypervalent bond.

These structures were discussed in reviews and papers. Some crystallographic data of their TBP fragments (the two apical bond lengths of the germanium and, where available, the displacement (Δ) of the Ge atom from the plane of three equatorial ligands) are summarized in Table 40.

The structure of 1-methyl-2-(1-germatranyl)-1,2-dicarba-closo-dodecaborane was recently determined. The N → Ge and C–Ge bond lengths were found to be 2.171 and 2.004 Å, respectively; the N–Ge–C angle is 177.7°.

The interatomic N → Ge distance is longer than the sum of the covalent radii by a significantly greater amount than the sum of the van der Waals radii of these elements (Table 1). After redetermination of the structure of 1-fluorogermatrane (191a), the shortest N → Ge distance (2.09 Å) was found in 1-fluorogermatrane (201 Å) in di(1-germatranyl)methane (215). These values are similar to those in neutral silatranes: the shortest Si–N distance (2.01 Å) was found in 1-fluorosilatrane and the longest (2.38 Å) in 2-(1-silatranyl)ethylsilatrane. In Si and Ge analogues with the same substituents, the N → M (M = Si, Ge) distance is generally 0.03–0.08 Å longer for germanium (the covalent radii of Ge is longer by 0.05 Å, Table 1). For example, in 1-ethylatranes the corresponding distances are 2.24 Å (Ge) and 2.21 Å (Si).

Gradual increase of the electron withdrawing effect of the substituent X at the central atom, e.g. from C2H5 to ICH2 to Br, leads to shortening of the N → Ge distance (2.24 → 2.19 → 2.09 Å, respectively). However, similar to the (O–M)-chelate derivatives of amides with the HalMe2MCH2N(M = Si, Ge) fragment (Section VI.A.1.c) and to 1-fluoro- and 1-chlorosilatranes, the N → Ge bond length in haloatranes increases in the series of Br < Cl < F, i.e. not in accordance with the electronegativity of the halogens but in the order of their ability to act as a leaving group in the nucleophilic substitution reactions. The N → Ge–X angle in germatranes is close to 180° and in most cases falls in the range of 176–179°. The only exception is p-tolylgermatrane (189d), where the angle is 144.2°.

It was suggested that the decrease of the C–Ge–O angles and ΔGe values in the crystal lead to intramolecular interaction between one of the O atoms of the atrane fragment and the H atom of the methyl group, which results in the noticeable distortion of the N → Ge–C bond.

An important characteristic of the geometry of the atrane fragment and the strength of the N → Ge interaction is the deviation of the Ge atom (ΔGe) from the plane of equatorial oxygen atoms toward the apical X substituent. For the germatranes studied (Table 40) the ΔGe values are in the range of 0.10–0.30 Å and increase with the N → Ge distance. For neutral silatranes the ΔSi range is ca. 0.10–0.24 Å. The correlation between the d(N → Ge) and ΔGe values is described by equation 54a:

\[
\Delta Ge = 0.72d(N-Ge) - 1.37 \quad r = 0.960 (n = 14) \quad (a)
\]

\[
\Delta Si = 0.61d(N-Si) - 1.24 \quad r = 0.970 (n = 32) \quad (b)
\]

Strengthening of the N → Ge interaction in Ge-substituted germatranes leads to a gradual decrease in the GeOC valent angles from 121.0 to 115.8° and to irregular changes of torsion OCCN (34.5–45.3°) and OGeNC (10.6–20.5°) angles. The nearly constant

ᶜFor -Ge[OCH₂CH₂]₃N.
ᵈTwo independent molecules in the unit cell.
ᵉ-n-Bu₂Sn[OOCCH₂CHRGe(OCH₂CH₂)₃N]₂ · H₂O (214a) (R = p-CIC₆H₄).

<references>
distance of the N atom from the equatorial plane of the three O atoms (1.97–2.00 Å) and from the plane of the neighboring C atoms (0.37–0.42 Å) testifies to the conservation of the atrane (OCH₂CH₂)₃N fragment. Thus, the length of the transannular N → Ge bond is mostly affected by the deviation of the Ge atom from its equatorial plane.

The length of the Ge–X bond (the shortest value of 1.757 Å for siloxygermatrane 206d⁵⁸⁹, the longest value of 2.360 Å for bromogermatrane 191c⁵⁹⁵) depends on the nature of the ligand and changes in reverse order of the N → Ge distance. The strength of the N → Ge interaction has almost no effect on the equatorial bond lengths (1.77 ± 0.01 Å); however, the latter values are slightly longer than that in tetraalkoxygermanes (1.75 Å). The close values of the Ge–Oₐx and Ge–Oₑq distances in organoxygermatranes 181a and 198 impede the interpretation of the N → Ge–O axial fragment geometry within the theory of hypervalent interaction⁶⁰¹. According to the theory, the equatorial Ge–O bonds should be shorter than axial⁵⁷³. Similar behavior was demonstrated by 1-methyl-2-carbagermatrane for Ge–C distances (see below).

Introduction of additional acceptor thienyl substituents at the silicon in siloxygermatranes 207 increases the SiOGe angle (133.0° for 207a, 134.8° for 207b, 139.6° for 207c and 180° for 207d)⁵⁸⁹.

Two crystallographically independent molecules of 1-hydroxygermatrane (190a)⁵⁹⁷ and 1-hydroxy-4-ethylgermatrane (198)⁵⁷³ are associated into dimers. Relatively longer N → Ge bond lengths (2.166 and 2.185 Å) in 198⁵⁷³ compared with 190a (2.146 Å) may be due to a steric effect of the 4-ethyl group. 3,7,10-Trimethyl-substituted germatranes⁵⁷²,⁵⁸¹, silatranes⁶⁰² and stannatranes⁶⁰³ consist of a mixture of diastereomers⁶⁰⁴,⁶⁰⁵ which hinders the interpretation of the X-ray data for these compounds.

A linear dual substituent relation between the chemical shifts of the germatrane protons (extrapolated to infinite dilution in CDCl₃) and the inductive (σ₁) and resonance (σ₀) substituent parameters at the Ge atom was found (equations 55, r = 0.99)⁶⁰⁶.

\[
\begin{align*}
\delta\text{OCH}_2 &= 3.809 + 0.391\sigma_1 + 0.035\sigma_0^0 \\
\delta\text{CH}_2\text{N} &= 2.840 + 0.322\sigma_1 + 0.043\sigma_0^0
\end{align*}
\]

(55)

The variation in the proton shielding results from the inductive influence of the X substituent and is approximately the same for both OCH₂ and CH₂N protons. Thus, the influence is transmitted not only through the system of covalent bonds but also through the N → Ge intramolecular coordination.

The inductive and resonance constants of the pentacoordinate -Ge(OCH₂CH₂)₃N moiety (σ₁ = –0.23 and σ₀ = 0.053) and the tetracoordinate -Ge(OCH₂CH₃)₃ group (σ₁ = 0.29 and σ₀ = 0.136) were obtained from the correlation of the δ¹³C values of the meta and para carbon atoms in mono-substituted benzenes⁶⁰⁷. The difference between the σ₁ values (Δσ₁(Ge) = 0.52) was attributed to the N → Ge intramolecular interaction in the former. A smaller value for the corresponding silicon compounds (Δσ₁(Si) = 0.43)⁶⁰⁸ is related to the higher N → M interaction in germatranes (M = Ge) as compared to silatranes (M = Si).

The ¹⁵N chemical shifts of 1-substituted germatranes in DMSO vary linearly with the σ* constants of the substituent X (equations 56), which influence is transmitted through the X–N → Ge hypervalent bond⁶⁰⁹. The decrease of the ¹⁵N shielding on the increase of both the electronegativity of X and the solvent polarity indicate a strengthening of the transannular bond⁶¹⁰–⁶¹². The smaller slope for Taft’s equation in germatranes (2.52)⁶⁰⁹ compared with silatranes (3.54)⁶¹³, as well as the smaller difference of the ¹⁵N chemical shifts for the solvent changes [(δ¹⁵N(CCl₄) → δ¹⁵N(DMSO)], reflect a stronger N → Ge than N → Si interaction in atranes⁶¹⁴,⁶¹⁵.
\[ \delta^{15}\text{N}(\text{Ge}) = 2.52\sigma_X^* - 367.2 \quad r = 0.99, n = 9 \]  
\[ \delta^{15}\text{N}(\text{Si}) = 3.54\sigma_X^* - 356.8 \quad r = 0.99, n = 10 \]  

The chemical shifts of the equatorial \(^{17}\text{O}\) atoms in alkoxygermatranes are very close to those in tetraethoxygermane. However, the shielding of the axial oxygen in ethoxygermatranes is by 14 ppm lower than that in tetraethoxygermane, indicating the predominant trans-influence of the \(\text{N} \rightarrow \text{Ge}\) coordination in germatranes.

In alkoxygermatranes the \(\delta^{73}\text{Ge} = -55.2\) (R = H), -60.6 (R = Me), -63.4 (R = Pr), -73.8 (R = SiMe\(_3\)) are shifted upfield compared with \(\delta^{73}\text{Ge} = 36.0\) ppm for the tetrahedral Ge(OMe)\(_4\). Similar upfield shifts of \(^{29}\text{Si}\) signals were detected for the corresponding silatranes. However, mass spectrometric studies of these compounds indicate either a weakening or absence of such interaction in the gas phase.

The transannular interaction in germatranes is explained by the model of hypervalency that assumes the formation of a three-center four-electron \(\text{N} \rightarrow \text{Ge} \rightarrow \text{X}\) hypervalent bond. This model successfully explains the trans-influence in such fragments, i.e. the inverse interdependence and the constancy of the sum of \(\text{Ge} \rightarrow \text{X}\) and \(\text{Ge} \rightarrow \text{N}\) bond orders. The calculated energies of the transannular bonds in some germatranes are higher than those in the corresponding silatranes.

The MNDO method gives a satisfactory explanation for the relatively close values of the \(\text{N} \rightarrow \text{Ge}\) distances in the calculated isolated molecules and in the crystals of germatranes. Due to the crystal field effect the \(\text{N} \rightarrow \text{Ge}\) bond lengths in the crystals are somewhat shorter than that in isolated molecules. The extremely short \(\text{N} \rightarrow \text{Ge}\) bond in the fluorogermatrane can be ascribed not only to the presence of electron-acceptor substituents but also to a strong crystal field influence.

There is a linear correlation between the calculated \(\text{N} \rightarrow \text{Ge}\) bond length and the effective charge on the nitrogen atom \(|q_N|\) calculated by MNDO (equations 57).

\[ d(\text{N-Ge}) = 13.589|q_N| - 3.322 \quad r = 0.994\quad(n = 7) \] (57)

Some geometric characteristics of some metallatranes \(\{\text{N(}CH_2CH_2O)\}_3\text{M} \rightarrow \text{X}; \text{M} = \text{Si, Ge, Sn}; \text{X} = \text{F, Cl, Br, H, Me}\} \) were calculated by the DFT method and linear correlations between bond lengths \(d(\text{M-Ge})\) and \(\sigma_1\) constants of X were revealed (equations 58). These data indicate an increase in the strength of the coordination in the three-center bond in the series of Si < Ge < Sn.

16. Hypervalent compounds of organic germanium, tin and lead derivatives

\[
d(N-Si) = -0.406\sigma_1 + 2.485 \quad r = 0.998 \; (n = 4)
\]
\[
d(N-Ge) = -0.189\sigma_1 + 2.393 \quad r = 0.989 \; (n = 5) \quad (58)
\]
\[
d(N-Sn) = -0.086\sigma_1 + 2.416 \quad r = 0.987 \; (n = 5)
\]

Assuming that the sum of the X–Ge and Ge–N bond orders is constant and equal to 1, the calculated N → Ge bond order is equal to 0.33, a value slightly higher than that in silatranes (0.30)\(^{621}\).

2. Homogermatranes, germatranones, carbagermatranes, thia- and azagermatranes

Tricyclic germatran analogues may be prepared by the same methods as germatranes. 1-Substituted 3-homogermatranes \((216)\) were synthesized from 3-hydroxypropyl-di(2-hydroxyethyl)amine. Reactions of the latter with MeGe(OEt)\(_3\) or organogerma-sesquioxanes lead to 1-methyl-3-homogermatrane in the first case or to 1-phenyl- and 1-(1-naphthyl)-3-homogermatranes in the second. The N-TMS derivative of the amine reacts with trifunctional germanes RGeX\(_3\) (X = Cl, Br, I, OEt; R = Alk, Ar, X) to give a series of homogermatranes \((220)\)\(^{624}\).

\end{align*}
\]

The ability of the pentacoordinated Ge atom in atrane to further extend its coordination number was demonstrated by the formation of adducts of aminotriacetic acid derivatives (germatranones) with DMSO, DMF or H\(_2\)O. For example, germatrane-3,7,10-triones XGe(OOCCH\(_2\))\(_3\)N (\((217a)\) (X = Me, Et, Ph) were isolated as 1 : 1 adducts with DMF and DMSO from transalkoxylation reaction between aminotriacetic acid and XGe(OEt)\(_3\)\(^{444,557}\), and also from the reaction of the tris(trimethylsilyl) ester of the acid with RGeCl\(_3\) (R = Cl, Me, Et)\(^{625}\). At high temperatures the adduct \((217a)\)-DMF(R = Me) undergoes elimination.
1070 Yuri I. Baukov and Stanislav N. Tandura

of DMF molecule and forms 1-methylgermatran-4,7,10-trione. Similar reactions of the corresponding aminoacetic acids or their TMS analogues lead to germatran-3,7-diones XGe(OOCC)2(OCH2CH2)N (218) and germatran-3-ones XGe(OOCC)2(OCH2CH2)2N (219) (X = Cl, Me, Et, Ph).

According to X-ray data, the substitution of one OCH2 group in the germatrane framework with an OCO fragment in 219a (X = Ph) does not affect the transannular N→Ge bond length (Table 42). However, further increase in the number of OCO fragments in compound 217b·H2O leads to shortening of the N→Ge bond, although the ΔGe value (0.17 Å) remains almost the same as in 189a·H2O (0.16 Å, Table 42). In these two compounds the Ge atom is hexacoordinated as a result of interaction with the H2O molecule.

The first carbagermatanes, 2-carbagermatanes 220 (X = Me, Et, Ph), were prepared from 3-chloropropylgermanes X(EtO)2Ge(CH2)3Cl and diethanolamine in the presence of Et3N.

In 1-methyl-2-carbagermatrane (220a) replacement of one oxygen atom with the less electronegative and bulkier CH2 group (with a van der Waals radius of 2.00 Å) elongates the N→Ge bond by 0.10 Å. However, the unexpectedly longer equatorial Ge−C distance (1.979 Å) compared with the axial bond (1.957 Å) indicate that steric factors and rigidity of the CGeC valent angle (which is only by 3° smaller than tetrahedral) affect significantly the geometry of the atrane framework.

The ionic component of the axial covalent Ge−X bond in the hypervalent N→Ge−X fragment increases on strengthening the N→Ge coordination. For example, the Ge−C bond length in 1-t-Bu-germatrane 118b (1.971 Å) is longer than that in 1-methyl-2-carbagermatrane 220a (1.957 Å) while the N→Ge coordination in the former (2.238 Å) is stronger than in the latter (2.436 Å). In turn, the Ge−X bond length in 1-bromo- (2.369 Å) and 1-chloro-germatrane (2.209 Å) is also longer than in the tetracoordinate GeBr4 (2.27 Å) and MeGeCl3 (2.135 Å).

16. Hypervalent compounds of organic germanium, tin and lead derivatives

Synthesis of 1-chloro-2,8,9-carbagermatrane (221) by trans-metallation reaction of trialkylamine and GeCl₄ in the presence of zirconium compounds (equation 59) was reported recently. Subsequent reactions with organomagnesium or organolithium derivatives lead to 1-organyl-2,8,9-carbagermatranes (222) (e.g. R = Bu, Ph, Vin, All).

\[
(CH_2=CHCH_2)_3N \xrightarrow{1. \text{Cp}_2\text{ZrHCl, THF, 0 °C}} \xrightarrow{2. \text{GeCl}_4} \text{Cl}\text{GeNClGeN}(\text{221})
\]

\[
\text{RMgBr or RLi} \rightarrow \text{R}\text{GeN}(\text{222})
\]

In reaction with aryl bromides in the presence of Pd₂(DBA)₃·CHCl₃/PAr₃ (DBA = dibenzylideneacetone) the carbagermatranes 222 displayed higher reactivities than the corresponding tributylgermanes. It was suggested that this is a result of the presence of transannular N→Ge bond in the atrane compounds.

Reaction of tris(2-mercaptoethyl)amine with carbofunctional trialkoxygermanes or organogermasesquioxanes gives trithiagermatranes (X = OH, OMe, OEt, NH₂; R = H, Ph). They are more hydrolytically stable than their oxygen analogues. According to X-ray data, trithiagermatrane (223a) (X = OH, R = H) has atrane structure while the corresponding oxygen analogue exists in the solid state as a spirocyclic lactone. The Ge-N distance in 223a (2.63 Å) is longer than that in aminocarbonyl and methoxycarbonylgermatranes 188i and 188k (2.19 and 2.24 Å) as a result of a decreasing electron supply to germanium due to the low electronegativity of sulfur compared with oxygen.

The first azagermatranes 224, namely 1-alkylazagermatranes 224a,b,d–f, were prepared in 1993 by transamination reactions (equation 60). By the same method n-butyl and allylazagermatranes 224c, 224g–i and haloazagermatranes 224j–m were prepared later. Haloazagermatranes 224j and 224l were isolated as relatively stable complexes and the reaction by-product was Me₂NH. Halo-N,N',N''-trimethylazagermatranes 224k and 224m are more stable than their unsubstituted analogues and may be isolated as moisture-sensitive compounds.

Recently, only few reactions of azagermatranes have been reported. In the presence of (H₂NCH₂CH₂)_3N the N,N',N''-trimethylazagermatranes 224b and 224e were converted into azagermatranes 224a and 224d, respectively. Reactions of azagermatranes 224a,b,d,e with TEAA lead to replacement of the azatran ligand by an atrane fragment. Reaction of the bromide 224m with BuLi demonstrates the possibility of substitution of the halogen in 1-haloazagermatranes by alkyl groups.
VII. PENTACOORDINATE INTRAMOLECULAR NEUTRAL TIN AND LEAD COMPOUNDS

A. Monocyclic Complexes

The most intensive studies in higher coordinated tin and lead compounds were carried out in the 1970–1990 period and the topic has been extensively reviewed up to 1992, particularly the investigations of complexes containing monoanionic C,D-chelating ligands (D = N, O). These compounds with the hypervalent pattern XSnC3D are good model substances for nucleophilic substitution at the tin atom and map the tetrahedron (T)–trigonal-bipyramidal (TBP) path. A comprehensive survey exists on organotin complexes containing bidentate imidazole- and pyrazole-type ligands.

1. Derivatives with bidentate C,N- and C,P-chelating ligands

a. Tetraorgano compounds. In contrast to germanium, higher-coordinated tetraorganotin compounds are known when electron-donating built-in ligands are present in a suitable position. Earlier examples, in particular of compounds with an intramolecular N → Sn interaction, were discussed in reviews. Among them, two series of compounds were reported containing the 8-(dimethylamino)-1-naphthyl (Np N) and 3-(2-pyridyl)-2-thienyl (PyTh) ligands. Most recently, chiral nonracemic tetraorganotins containing one or two (−)-(1R,2S,5R)-menthyldimethylsilyl (Men) substituents were obtained by reaction of an excess of NpNLi with MenPh2SnF or Men2PhSnI, respectively. The tetraorganotin derivative with 2-(4-dimethylamino-2-methyl-2-azabutyl)phenyl (PhNN) ligand was also described.

X-ray crystallography of tetraorganotin compounds show a five-coordinated tin with a strongly distorted TBP geometry due to a weak intramolecular N → Sn coordination, with three of the carbon atoms at approximately equatorial positions and the nitrogen atom and the fourth carbon atom at the axial sites (Table 43). The N → Sn coordination bonds are extremely long (2.84–2.90 Å), and the Sn–C bonds...
trans-orientated with respect to the nitrogen are slightly elongated (at ca. 0.035 Å) as compared with the other bonds.

The electron lone pair at N in 227 points toward Sn (N···Sn distance of 3.153 Å) and the coordination tetrahedron at Sn is only slightly distorted toward a TBP \(^{641}\). This interaction is weaker than those in tetraorganostannanes 225a, 225b and 226a. The Mossbauer spectra of 226 are in agreement with the pentacoordinated tin atom in these compounds\(^{639}\). In compound [Me\(_2\)(Cl)SnOC\(_6\)H\(_4\)CH\(_2\)N(Me)CH\(_2\)CH\(_2\)NHMe\(_2\)]Cl \cdot HCl, a much stronger N→Sn interaction is found (2.574 Å) and the inner nitrogen atom is trans to the electronegative chlorine substituent (169.3°). An interaction of the second amino group with the Sn atom is not possible because the Lewis basic center is blocked by the addition of HCl.\(^{641}\)

In solution, the tin centers in 225 and 226 are also pentacoordinated, as indicated by an increase of the \(^1J(\text{\textsuperscript{119}Sn}-\text{\textsuperscript{13}C})\) value in the \textsuperscript{13}C NMR spectra and the high-field shift of the \textsuperscript{119}Sn resonance in the \textsuperscript{119}Sn NMR spectra\(^{638,639}\) (Table 43). Besides, the \(^1H\) and \textsuperscript{13}C NMR spectra of chiral 225b show two resonances for the diastereotopic NMe\(_2\) group, indicating the absence of pyramidal inversion of the nitrogen\(^{638}\).

In contrast, according to the \textsuperscript{119}Sn chemical shifts and the \(^1J(\text{\textsuperscript{119}Sn}-\text{\textsuperscript{13}C})\) or \(^2J(\text{\textsuperscript{119}Sn}-\text{\textsuperscript{1}H})\) values, a tetrahedral geometry at tin is suggested for Me\(_2\)N(CH\(_2\))\(_3\)SnPh\(_3\) (228)\(^{644}\), and for the ferrocenyl derivative 2-Me\(_3\)SnFcCH\(_2\)NMe\(_2\) (229) and its analogues with potential C,P- and C,O-coordinating ligands, 2-Me\(_3\)SnFcCH\(_2\)PPh\(_2\) (230) and 2-Me\(_3\)SnFcCH\(_2\)POPh\(_2\) (231)\(^{643}\). The geometry of 230 in the solid state displays a P···Sn contact longer than 4 Å (Table 1).

---

Examples of enhanced reactivity in halodemetalation reactions of mixed tetraorganotin compounds, in which potentially coordinating groups, in particular the Np N ligand, are present in the \(γ\)-position with respect to tin, are discussed in a review\(^{636}\) and papers\(^{645–647}\). It is suggested that the intramolecular assistance by those groups facilitates the cleavage of Sn–C bonds \(trans\) to them.

**b. Triorganotin hydrides.** The examples of surprisingly relatively stable triorganotin hydrides containing one monoanionic C,N-chelating ligand that have been studied are depicted in Scheme 11. These compounds include the following ligands: \(3\)-(dimethylamino)propyl (Pr\(_N\)) in \(^{232}\)\(^{648}\), \(2\)-[(dimethylamino)methyl]phenyl (Ph\(_N\)) in \(^{233a–d}\)\(^{648}\), the chiral \(2\)-[(1S/R)-1-dimethylaminoethyl]phenyl (Ph\(_N^*\)) in \(^{234a–c}\) and \(2\)-[(1S)-1-dimethylamino-2,2-dimethylpropyl]phenyl (Ph\(_N^*\)) in \(^{234d}\) and \(^{234e}\), NpN in \(^{235a–d}\)\(^{648}\), \(2\)-(4,4-dimethyl-2-oxazolinyl)-5-(methyl)phenyl (Ox\(_N\)) in \(^{236a}\) and \(^{236b}\), and the chiral 2-(4-isopropyl-2-oxazolinyl)-5-(methyl)phenyl (Ox\(_N^*\)) in \(^{237a}\) and \(^{237b}\). These hydrides are generally obtained from the LiAlH\(_4\) reduction of the corresponding triorganotin bromides and the NaBH\(_4\) reduction of the chlorides\(^{640,650}\).

Among the organotin hydrides, the chiral compounds have received considerable attention in recent years as enantioselective free radical reducing agents\(^{650,651}\). The first representative of the optically active tin hydrides containing a potentially bidentate chelating ligand, \(^{235b}\), including a stereogenic tin atom with the NpN ligand and the chiral Men substituent, was synthesized by Schumann and coworkers\(^{642}\). Starting from (−)-methyl chloride, the corresponding Grignard reagent reacts stereospecifically with Me\(_3\)SnCl to give Me\(_3\)MenSn which was derivatized by selective bromodemetalation, alkylation and finally hydrogenation to yield \(^{235b}\) as a mixture of epimers differing in the absolute configuration at the tin center in a 40 : 60 ratio in solution. X-ray crystallography of \(^{235b}\) revealed a pair of \(R_{Sn}/S_{Sn}\) epimers, with the coordination geometry around tin for the two molecules in the asymmetric unit being ‘a trigonal-bipyramidal-like monocapped tetrahedron’.

---

\(^{636}\) Deviation of the tin atom from the quasi-equatorial plane toward the pseudo-axial carbon atom; the sum of the ‘equatorial’ angles is given in parentheses.

\(^{645–647}\) Two independent molecules in the unit cell.

\(^{648}\) Sn–H 1.52 Å.

\(^{649}\) Sn–C(Me\(_3\)).

\(^{650}\) Sn–H 1.63 Å.

\(^{651}\) P···Sn.
A main feature of the arrangement at tin is a quasi-equatorial position of hydrogen and a quasi-axial position of the \( t \)-butyl group as well as the coordinating nitrogen atom, suggesting an early stage of an \( S_N2 \)-like approach of the donor atom toward the central atom \( \text{trans} \) to the \( \text{Sn}–\text{CMe}_3 \) bond. This feature relates 235b to the N-donor-substituted tetraorganotin compounds discussed above, taking into account similar N–Sn bond distances in all these compounds (Table 43). These distances are close to the limiting nonbonding distance between tin and nitrogen, 3.08 Å, defined by Dräger.535.

The estimation of the position of 235b along the \( T \rightarrow \text{TBP} \) pathway by using the difference between the sums of the equatorial and axial angles with values between 0 (ideal T) and 90° (ideal TBP)652 gives values of 21° and 14° for \( R_{\text{Sn}} \) and \( S_{\text{Sn}} \) epimers, respectively642.

The NMR spectral data of 232 indicate a coordination sphere of the Pr\( _\text{N} \) substituted organotin hydride similar to that of an unsubstituted hydride648. In particular, the two \( ^{117}\text{Sn}[^1\text{H}] \) resonances at \(-88.8 \) and \(-92.1 \) ppm are within the region of resonances of the likewise tetrahedrally coordinated tin, e.g., as in \( \text{Me}_2\text{MenSnH} \) (\(-96.8 \) ppm).
The $^{119}\text{Sn}$ NMR shifts of the tin hydrides 233 and 234 (δ about −120 to −130 ppm) are generally in the region of the values found for diaryl(monoalkyl)tin hydrides\textsuperscript{640,648,650}. Analogously, the absence of a high-field shift of the two $^{117}\text{Sn}$$^1\text{H}$ resonances of 235a at −108.5 and −125 ppm compared with those of unsubstituted MeMenNaphSnH (−117.0 and −121.6 ppm) is significant\textsuperscript{648}. These results suggest the absence of a significant donor–acceptor interaction between the tin and nitrogen atoms. Moreover, the $^{13}\text{C}$- and $^1\text{H}$-NMR spectra of 234b and 234b\textsuperscript{′} in C\textsubscript{6}D\textsubscript{6} at room temperature indicate equivalence of the nitrogen-bonded methyl groups of the PhN\textsuperscript{*} ligand for each diastereomer of 234b and 234b\textsuperscript{′}; indicating either no N → Sn coordination or a fast N → Sn association/dissociation on the NMR time scale\textsuperscript{640}.

Nevertheless, all $^1J(^1\text{H}−^{117,119}\text{Sn})$ coupling constants of the tin hydrides 233–235 are generally large compared to noncoordinated tin hydrides with similar substituents, showing a trend toward an intramolecular coordination at the tin atom and being in good agreement with the X-ray analysis of 235b\textsuperscript{642}, which indicates that the hydrogen atom is bound to the tin center in the equatorial position. Furthermore, in the case of the methylmethyl derivative, the methyl coupling constants, $^1J(^{13}\text{C}−^{117,119}\text{Sn})$ and $^2J(^1\text{H}−^{117,119}\text{Sn})$ are decreased, while the methyl coupling constant, $^1J(^{13}\text{C}−^{117,119}\text{Sn})$, is increased. This indicates also a distortion of the tetrahedral coordination around the tin toward the TBP geometries in these compounds, with the methyl group occupying a quasi-axial and the methyl group a quasi-equatorial positions\textsuperscript{648}. The tin hydride 234c shows an extremely high-field shift (δ = −188.8 ppm) as a result of a slightly stronger coordinative interaction due to the negative inductive effect of the additional phenyl substituent\textsuperscript{650}.

When compared to the PrN, PhN and PhN\textsuperscript{*} substituted organotin hydrides, the N → Sn coordination in the NpN derivatives 235c and 235d is stronger, as evidenced by NMR spectroscopy\textsuperscript{640}. In particular, the $^1\text{H}$- and $^{13}\text{C}$-NMR spectra of 235c at 20 and 100 °C in C\textsubscript{6}D\textsubscript{5}CD\textsubscript{3} contain two separate singlets and the $^1\text{H}$-NMR spectra of the two diastereomers of 235d at room temperature in C\textsubscript{6}D\textsubscript{6} contain four singlets, all associated with the two nonequivalent methyl groups attached to the nitrogen in the NpN moiety in each of the species.

Finally, the chemical $^{119}\text{Sn}$ NMR shifts of the extremely unstable organotin hydrides 236 and 237\textsuperscript{651} containing an oxazoline substituents are in the ranges of δ ca −62 to −64 and −122 to −148 ppm for the dimethyl and diphenyl derivatives, respectively. The $^{13}\text{C}$- and $^1\text{H}$-NMR spectra of the diastereomeric mixture of 236b display four separate signals corresponding to the two diastereomeric methyl groups of each isomer on the oxazoline ring, indicating that dissociation of the N−Sn bond is slow on the NMR time scale.

It is therefore evident that the weaker coordination of the tin hydrides compared to the tin halides (see below) is the result of the reduced Lewis acidity of the tin atom. The diastereomeric ratios of the triorganotin hydrides and the precursors tin halides in solution generally differ from unity (Table 44). In most cases the diastereomeric ratios are modest and higher for 234a\textsuperscript{650}. In the methyl derivatives 232, 233b and 235a, the diastereomeric ratios, which reveal an optical induction from the menthyl ligand to the asymmetric tin center, increase in an order of increasing rigidity of the potentially bidentate ligand, (PrN) < (PhN) < (NpN)\textsuperscript{648}.

Two different diastereomeric mixtures of (Rc)-234a were obtained, depending on the solvent used for the reduction\textsuperscript{650}. The ratios of both diastereomeric mixtures did not change for weeks, showing that the stereogenic tin center is configurationally stable. In addition, the tin hydrides 232, 233b and 235a show constant optical rotation values, indicating a constant ratio of diastereomers which are most likely stable toward interconversion\textsuperscript{648}. Moreover, heating a toluene solution of 235d at 100 °C for 20 minutes causes no change in the 66 : 34 diastereomeric ratio\textsuperscript{640}. Thus, the diastereomeric ratios of
16. Hypervalent compounds of organic germanium, tin and lead derivatives

*a Only one broad ¹¹⁷Sn resonance at −3.7 ppm is observed, indicating a fast dynamic process.
*b Determined by ¹¹⁷Sn[¹H] NMR.
*c Only one diastereomer was found in a freshly prepared solution, (Rₛₘ) for (R₅C)-MePhP₅N₅SnBr and MeMenP₅N₅SnBr.
*d Sₛₘ/Rₛₘ.
*e In Et₂O at 0 °C, the same ratio of the two isomers was obtained at −70 °C.
*f The ratio of the diastereomers is 58 : 42 for the reduction in THF at room temperature.
*g Determined by ¹¹⁹Sn NMR.
*h 30 : 70 (Sₛₘ/Rₛₘ) for a freshly prepared sample from methanol, 50 : 50 after 3 days.

The tin hydrides are usually the result of a kinetically controlled and stereospecific reduction of the corresponding tin halides. This distinguishes the diastereomeric tin hydrides from the corresponding diastereomeric tin halides, which are in a dynamic equilibrium (see below).

Nevertheless, epimerization was observed when the tin hydride (R₅C)-234a was treated with an excess of LiAlH₄ in THF. Furthermore, using THF as the solvent at room temperature, the reduction of the corresponding bromide gave a 58 : 42 diastereomeric ratio, i.e. under these conditions the reaction is thermodynamically controlled.

The almost nonselective formation of the tin hydrides 232, 234e and 236b is remarkable. In particular, in the case of 234e the authors suggest that the reduction occurs stereospecifically and that the minor diastereomer (S₅C,Rₛₘ)-t-BuPhP₅N₅*SnBr is reduced faster than the major diastereomer (S₅C,Sₛₘ)-t-BuPhP₅N₅*SnBr which is epimerized because of its configurational instability.
Data related to the enantioselectivity of organotin hydrides containing chiral PhN ligand in free radical reductions have been published. Reaction of the tin hydrides and with methanol was also reported to proceed with abstraction of H₂ and formation of the methoxy derivatives Me₂PhNSnOMe and MePhPhNSnOMe, respectively.

c. Triorganocompounds. Triorganotin halides containing one monoanionic C,N-chelating ligand have been well known since the 1970s as typical pentacoordinate compounds with a rather strong N → Sn coordination, mainly due to systematic investigations by Noltes, van Koten and Jastrzebski. The main representatives of these compounds include the following types of five-membered ring ligands (Scheme 12): PrN and PhN, chiral PhN, and chiral PhN. Triorganotin chlorides and bromides with the ligands shown in Scheme 12 are generally prepared by the reaction of 1 : 1 diorganotin dihalides with the PrN or ArN lithium reagents. In specific cases, arylcopper compounds or arylgoldlithium derivatives were used. Fluoride was obtained by treatment of chloride Men₂NpNSnCl with KF in acetone.

Early examples of related compounds, in particular those including 2-(phenylazo)phenyl ligand, i.e. 255a and 255b, or 2-{[(dimethylamino)methyl]phenyl}methyl and 8-(dimethylamino)methyl-1-naphthyl ligands, both containing a six-membered chelate ring, were discussed in a review. Various reactions, such as Grignard reactions, redistribution, halogenation, exchange of halide and phenylation, have been used for obtaining the series of compounds PrNPh₂SnX as well as the related derivatives (PrN)ₙPhₓSnClᵧ (x = 1–4, y = 0–3, z = 0–2), containing PrN as a potential intramolecular donor ligand. Note that attempts to substitute all the chlorine atoms of Ph₂SnCl₂ and PhSnCl₃ by the R group of the Grignard reagent failed and resulted in cleavage of a phenyl group, leading to the triorganotin derivatives, with KF in acetone.

The hydrochloride, compounds (X = Br, I, S₂CNR₂, OCO₂R, where R = Me, Et, Ph) containing 2-ethylpyrldyl ligand, as well as thienyl triorganotin species, in which the heterocycle contains 3-(2-pyridyl) or 2-(2-oxazolinyl) substituents, and 266 (R = Me, n-Bu, n-Hexyl, Ph, p-Tol; X = Cl, Br, I, OH, S₂CNMe₂) were recently described. X-ray crystallography of shows a TBP arrangement at the tin atom due to intramolecular coordination by the inner nitrogen atom, with a dangling CH₂CH₂NHMe₂⁺ group. A series of 2-stannyl-substituted ferrocenylmethyl-amine and -phosphine derivatives 2-XMe₂SnFcCH₂D (X = Me, Cl; D = NMe₂, PPh₂, POPh₂), with the ferrocenylene group spanning the two potential coordinating sites, were recently obtained.

The tetraorganotin was prepared from Me₂SnCl and 2-LiFcCH₂NMe₂; it was transformed into phosphine through intermediate methiodide according to equation 61. The tin monochlorides and were synthesized by the redistribution of and with Me₂SnCl or Me₂SnCl₂, respectively. The oxidation of with H₂O₂ in Et₂O leads to . The monochlorination of the latter to yield was achieved with HCl in ethanol.
16. Hypervalent compounds of organic germanium, tin and lead derivatives

SCHEME 12. Triorganotin halides containing one five-membered C,N-chelating ligand
Earlier series of compounds containing a C,P-chelating ligand, the tertiary phosphine derivatives 271a–d, was also described\textsuperscript{201,204}.

The Pb analogue of 258a, i.e. the triphenyl derivative 272a, was prepared by phenylation of PbCl\textsubscript{2} with PhLi and subsequent reaction with 3-dimethylaminopropyl chloride\textsuperscript{658}. One phenyl group from 272a was cleaved with HCl, HBr or HI to yield the monohalides 272b–d, respectively.

Selected crystallographic and NMR data pertinent to the TBP structures for pentacoordinate triorganotin and triorganolead complexes containing aliphatic and aromatic N-donor ligands are collected in Tables 45–47.

In the solid, all the compounds have essentially TBP coordination geometry with the carbon ligands at the equatorial sites and the more electronegative nitrogen and halogen or sulfur atom at the axial positions. The solid state geometries are largely retained in solution as deduced from \textsuperscript{1}H, \textsuperscript{13}C and \textsuperscript{119/117}Sn NMR spectroscopic studies. For instance, comparison of the \textsuperscript{119}Sn-NMR chemical shifts of tin bromides (\(S_c,S_{Sn}\)- and (\(S_c,R_{Sn}\))- 245b (−103.2 and −98.2, CDCl\textsubscript{3}), (\(S_c\))-245c (−121.7, C\textsubscript{6}D\textsubscript{5}CD\textsubscript{3}), (\(S_c,S_{Sn}\)- and (\(S_c,R_{Sn}\))-248b (−100.3 and −93.1, CDCl\textsubscript{3}) with the corresponding data for diphenyl(neomenthyl) tin bromide (\(\delta = −5.91\)) shows a large high-field shift of approximately 100–120 ppm\textsuperscript{650}. Additional examples of \textsuperscript{119}Sn-NMR chemical shifts for pentacoordinated triorganotin complexes with the Ar\textsubscript{N} moiety are given in Table 47.

<sup>a</sup>Measured in CD<sub>2</sub>C<sub>2</sub>Cl<sub>2</sub>.

<sup>b</sup>Not obtained.

<sup>c</sup>Hexacoordinated tin.

With a Burgi–Dunitz-type of analysis<sup>261, 262, 475</sup>, which was discussed in Section VI.A.1.c, the variations in the geometry of the pentacoordinate neutral intra- and intermolecular complexes with TBP geometries were analyzed in detail<sup>636</sup>. The axial arrangement of a donor atom D, in particular nitrogen, and a substituent X in compounds with central coordination unit DSnC<sub>3</sub>X was considered as a representation of different points (a ‘snapshot’) along a hypothetical reaction coordinate of a S<sub>N</sub>2 pathway for substitution with inversion at tetrahedral tin. The experimental data in relation to the interdependence of the differences between D–Sn and Sn–X bond lengths in pentacoordinate and tetrahedral compounds, and the averaged DSnC and CSnX angles, fit very well the theoretical curves. The latter were deduced by using the Pauling relationship between bond length and bond order<sup>474</sup>, where \( d(n) \) is the bond length, \( d(l) \) is the single bond length and \( c \) depends on the type of bond (equation 62).

\[
\Delta d(n) = d(n) - d(l) = -c \log n

</table>

For selected compounds, $\delta^{119}$Sn relative integral ratio: 46 : 54.

Two correlations were established: as D–Sn becomes shorter, the Sn–X distance tends to become longer and the average DSnC angles tend to become larger.

Another parameter, which also served as a probe for the progress of the S12 reaction, is the deviation of tin atom from the equatorial plane, ∆Sn (Tables 43, 45 and 47). Thus,
the tetraorganotins and hydride 235b (Table 43) represent an early step in the reaction (ΔSn ca 0.45–0.57 Å), while for the triorganotin derivatives (Tables 45 and 47) the progress of the reaction is more advanced (ΔSn ca 0.20 Å). The highest extent of a goodness of a TBP environment at tin takes place for six-membered chelate 257b (ΔSn 0.06 Å).

Factors affecting the increase of coordination at Ge, Sn or Pb were discussed for the tin compounds 239, 258–260 containing the PrN moiety, and also for their Ge (Section V.A) and Pb analogues, in which the Me2N donor intramolecularly coordinates the central atom658. The X-ray and 13C, 119Sn and 207Pb NMR data (Tables 45 and 46), the model of the 3c–4e interaction N → M−Xax and the structure correlation results673 were used for this purpose. It is suggested that the nucleophilic coordination originates from the π-basicity and the charge flow from the ligands into the σ∗-LUMO at the central atom. The values of 119Sn NMR chemical shifts and spin–spin coupling constants support the arguments in favor of interactions of the frontier orbitals. The δ13C values of the α-methylene group in CDCl3 solution are shifted distinctly to high frequency, which indicates the approach of the Me2N donor to the central atom. The electronegativity decrease of the ligands at Ge, Sn or Pb inhibits intramolecular nucleophilic attack658. In the ligand sequences PhCl2 > Ph2Cl > Ph3 and Ph2I > Ph2Br > Ph2OPh > Ph2F the N → Ge/Sn/Pb distance becomes smaller. With regard to the halide substituents, the chemical shift sequences δ(119Sn) (Br ≫ Cl > F > I) and δ(207Pb) (Br > Cl > I) are similar.

The X-ray structures of 239b–e and 272d show an almost equal deviation of the central atom from an ideal TBP arrangement658. In particular, the latter is displaced 0.14–0.16 Å out of the equatorial plane in a direction away from Nax, with the XaxSnNax angle in the narrow range of 167.7–167.9° for X = Hal (Table 45). Moreover, the N–Sn/Pb distances transformed into Pauling bond orders are almost equal (0.21–0.23). Furthermore, the goodness of their TBP geometries, defined as the difference ΔΣ(θ) of the sums of equatorial and axial angles (see below), is 75–77° (ΔΣ(θ) = Σθeq − Σθax, ΔΣ(θ) = 0° for a perfect tetrahedron and 90° for a perfect TBP).

X-ray determinations of the dithiocarbamates 264a and 266b reveal a TBP structure, with the nitrogen and sulfur atoms in the axial positions664,665. The 2-ethylpyridyl and 3-thienyl-2-(3-oxazolinyl) ligand chelate the tin, while the dithiocarbamate is monodentate. The N → Sn interaction in the latter is weaker and the extent of distortion from a TBP structure is larger (Table 47).

Both crystal structure determinations and NMR studies in solution show for 267b, 268b and 269b molecular structures in which the tin atom approaches a TBP pentacoordination as a consequence of an intramolecular D → Sn interaction643. In contrast to the tetraorganotin derivative 268a, the P–Sn distance of 3.349 Å in chloride 268b is shorter than the sum of van der Waals radii (Table 1), indicating a weak P → Sn interaction and suggesting the ligand polyhedron at tin as a monocapped tetrahedron (T). This interaction is weaker than that in the related structure of 271d204 due to the higher donor capacity of the t-BuPhP group and the greater flexibility of the chelate ring in the latter compound.

The extent of distortion of 267b–269b on the pathway between the ideal T and the ideal TBP is determined by three parameters: (i) the difference Σθeq − Σθax (deg) between the three equatorial CSnC angles and three axial CSnCl angles at tin, namely 90° for the TBP and 0° for T652; (ii) the deviation ΔSn (Å) of the tin atom from the plane through the three equatorial ligands in the tin polyhedron, which ranges from 0.71 Å for T to 0 Å
for the TBP; and (iii) the bond length differences $\Delta d(D \rightarrow Sn) - \Delta d(D-Sn)$ (Å) 
$D = N, P, O$; $d(N-Sn) = 2.08$, $d(P-Sn) = 2.52$, $d(O-Sn) = 2.02$, which decrease 
with increasing donor strength of the functional group $D$. All three parameters indicate 
an increase of the intramolecular coordination for the donor group in 267b–269b in the 
sequence $\text{Ph}_2P < \text{Me}_2N < \text{Ph}_2PO$. The observed $\delta^{119}\text{Sn}$ and 
$2J^{(119}\text{Sn}-\text{CH})$ values suggest for 267b and 269b TBP geometries at tin, while the $\delta^{119}\text{Sn}$ value of 268b indicates only a small tendency for 
an increase in the coordination number of tin in this compound.

The P $\rightarrow$ Sn coordination in 271a–d is relatively weak, as could be concluded from the 
observation that intermolecular coordination of external donors like pyridine, HMPA and 
DMF could compete with intramolecular P $\rightarrow$ Sn interaction. In solution of 268b and 
271d a fast equilibrium exists between tetracoordinated open-chain and pentacoordinated 
cyclic structures.

Contrary to tetraorganotins and triorganotin hydrides, triorganotin halides are gener-
ally configurationally unstable. It is well known that their configurational stability is 
significantly enhanced due to the presence of intramolecularly coordinating substituents. 
This gives chiral pentacoordinate, triorganotin halides with the tin atom as the center 
of chirality, as well as optically active tin bromide containing the C,N-chelating chiral 
$\text{PhN}^*$ ligand, which structure was proved by X-ray diffraction. Such tin com-
ounds containing a stereogenic tin center or chiral ligand are of particular interest 
both from a stereochemical point of view and as reagents, e.g. the chiral organotin hydrides 
in asymmetric synthesis (see above). Stereochemical aspects and fluxional processes in 
triorganotin halides containing one monoanionic C,N-chelating ligand were discussed 
in detail.

Two basic processes are in common operative in solution: (1) N–Sn dissociation/association and (2) inversion of configuration of the tin center. On the NMR time 
scale the former becomes fast for bromide above 30°C, while the latter does not 
occur or is at least slow up to 125°C. Nevertheless, inversion of configuration of the tin 
center takes places at low temperature on the laboratory time scale. For example, on dis-
solving enantiomerically pure bromide ($R_c$,$R_{Sn}$)-245a in toluene, the $^1H$ NMR spectrum 
at $-30°C$ shows the presence of only one diastereomer. At $-13°C$ an epimerization 
process starts which finally results in the formation a 40:60 mixture of the ($R_c$,$R_{Sn}$) and 
($R_c$,$S_{Sn}$) diastereomers. In addition, the reaction of $\text{PhN}^*$ with MenPh$\text{SnCl}_2$ in 
$\text{Et}_2\text{O}$ results in the formation of the two diastereomers in a 70:30 ratio at both 0°C 
and $-78°C$. Thus, the ratios of the tin halide diastereomers shown in Table 4 result 
from a thermodynamically controlled reaction of the precursor diorganotin dihalides with 
$\text{ArN}^*$ compounds.

Flexibility of the chelate ring has an important influence on the rate of inversion of 
configuration at tin. For the $\text{PrN}$ derivative 238, $^1H$ and $^{13}C$ NMR investigations show the 
presence of only one broad resonance pattern at an ambient temperature, which displays 
a tendency to decoalesce to two resonance patterns for the two possible diastereomers at 
low temperature ($-60°C$). However, at $-60°C$, the lowest temperature studied, only 
broadening of the Me–Sn and the NMe$_2$ signals took place. This suggests a comparatively 
fast inversion of configuration at tin due to the much more flexible chelate ring present 
in 238 as compared to both 243 and 251a.

The ratio of the two diastereomers depends significantly on the bulk of the substituents 
at the chiral benzylic carbon center. In particular, for the $t$-Bu-substituted 248a only 
one diastereomer ($R_c$,$S_{Sn}$) and for the Me$_3$Si-substituted 249a only one enantiomeric 
pair ($R_c$,$R_{Sn}$)/($S_c$,$S_{Sn}$) are present in solution. According to X-ray study, the same
enantiomeric pair is found in the solid state, where the bulky Ph−Sn and Me₃Si groups are at opposite sides of the molecule. From the ¹H DNMR investigations, in triorganotin bromides containing a six-membered chelate ring, 256a, 256b, 257a and 257b, both the N−Sn dissociation/association and inversion of configuration at tin processes are operative on the NMR time scale. In particular, for bromide 256b, the N−Sn dissociation/association process becomes fast at −30°C, while inversion of configuration of the tin center takes place above 0°C. In triorganotin bromides 251 containing the NpN ligand, N−Sn dissociation on the NMR time scale does not occur even at high temperature (125 and >100°C, respectively). A detailed discussion of the mechanism of inversion of configuration at tin centers having a TBP coordination geometry can be found elsewhere.

As a consequence of the asymmetry of 1,2-disubstituted ferrocenes and a stereochemically stable TBP configuration at tin, the two tin methyl groups in 267b–269b should be diastereotopic. Indeed, the ¹H NMR of 267b and 269b show two separate signals for these groups. In contrast, the N−Me groups in 267b are equivalent at room temperature, suggesting a N→Sn dissociation/association process, while the configuration at tin is stable on the NMR time scale.

The geometries and energies of the two tin epimeric diastereomers of 252b and 254b were optimized at the AM1 semiempirical technique. The calculations are in good agreement with the molecular geometry in the solid state as well as with the diastereomeric ratios observed in solution. In particular, the calculated N−Sn distances in (R-Sn)-252b and (S-Sn)−252b are 2.62 and 2.59 Å, respectively, while the X-ray determined value is 2.55 Å for (R-Sn)-252b. The calculations predict that (R-Sn)-252b is more stable than (S-Sn)-252b by 0.14 kcal mol⁻¹, which corresponds to an approximately 1:1 ratio of the isomers at 25°C (see Table 44).

d. Diorgano and monoorgano compounds. Earlier examples of diorganotin dihalides containing Ph₅N and Ph₅N C,N-chelating ligands, i.e. 273a−c and 274, and their complexation with pyridine were discussed in detail in a previous review.

\[
\begin{align*}
\text{(273) (a)} & : X = Cl, R = Me \\
\text{(b)} & : X = Br, R = Me \\
\text{(c)} & : X = Cl, R = Ph
\end{align*}
\]

\[
\begin{align*}
\text{(274) (S, S)} & : R = Me \\
\text{(274) (S, R)} & : R = Br
\end{align*}
\]

Based on the NMR and molecular weight data, the tin atom in these compounds is pentacoordinate and likely to have a TBP coordination geometry at tin in which the aryl and R groups reside in the equatorial plane. Of special interest is dibromide 274 containing two chiral centers with (S) configuration of the chiral benzylic carbon while the configuration of the chiral tin center may be either (S) or (R). Only one resonance
pattern in the $^1$H NMR spectrum is observed from $-80$ to $100°C$. This is most likely in agreement with a process of inversion of configuration at tin, which is fast on the NMR time scale even at very low temperature.

A proposed mechanism resulting in inversion of configuration at tin in dihalides 273 and 274 includes an achiral dimeric intermediate 275 with hexacoordinate tin centers (equation 63)$^{653}$. Evidence for such an intermediate is the observation of two Sn–Me resonances in the $^1$H NMR spectrum of a mixture of dichloride 273a and dibromide 273b in toluene-$d_8$ at $<-80°C$, while only one resonance pattern is observed at higher temperatures.

More recently, dichloride 259a and the corresponding diphenoxo derivative 259b containing the Pr$\text{N}$ moiety$^{644,658}$, as well as dichloride MePhNSnCl$_2$ (276)$^{656}$ have been prepared. An X-ray study of 276 revealed a TBP arrangement at the tin center with the two carbon atoms and a chlorine atom in equatorial positions and the coordinating nitrogen and the second chlorine atom in axial positions. As compared to monochloride 240a, the axial bond lengths in 276 are shorter and the deviation of the tin atom from the equatorial plane ($\Delta$$\text{Sn}$) toward the chlorine atom is larger (Tables 47 and 48), in agreement with the higher Lewis acidity of the tin atom in the latter.

A sequence analogous to the preparation of 259b from Me$_2$N(CH$_2$)$_3$MgCl (Scheme 13) was used for transformations Me$_2$NCH$_2$CH$_2$CMe$_2$MgCl $\rightarrow$ Me$_2$NCH$_2$CH$_2$CMe$_2$SnPh$_3$ $\rightarrow$ Me$_2$NCH$_2$CH$_2$CMe$_2$SnPh(0Ph)$_2$.$^{668}$ The latter reacted with two equivalents of Na$_2$S·9H$_2$O to give the diorganotin dimer 277. A similar dimeric derivative 278 containing one chelate and one nonchelate Si-substituted 1-(8-quinolinyl)methyl ligand at each of the tin atoms has been reported.$^{679}$ In contrast, its Se and Te analogues are found to be the monomeric bis-chelate derivatives (see below).
Rare examples of monoorganotin trihalides containing a C,N-chelating ligand are two series of imine derivatives, \( \text{279a–d} \)\(^680\) and \( \text{280a–d} \)\(^681\). X-ray crystal determinations of \( \text{279c} \) and \( \text{280b} \) revealed a distorted TBP geometry as a result of intramolecular \( \text{N} \rightarrow \text{Sn} \) coordination. Shortening of the axial bonds in trichlorides \( \text{279c} \) and \( \text{280b} \) as compared to mono- and dichlorides (see above) was observed (Table 48).

All the phenyl groups are cleaved off when \( \text{258a} \) is treated with ethylene glycol or with pinacol, resulting in the formation of \( \text{[PrNSn]}_2(\text{OC}_2\text{H}_4\text{O})_3 \) (\( \text{281} \)) and \( \text{[Me}_2\text{N(CH}_2)_3\text{Sn]}_2(\text{OC}_2\text{Me}_4\text{O})_3 \) (\( \text{282} \)), respectively\(^644\). Tetraphenyltin does not react with these diols under the same conditions, thus indicating the activating role of the dimethylaminopropyl group in \( \text{258} \). Compounds \( \text{281} \) and \( \text{282} \) are transformed almost quantitatively into \( \text{283} \) by reaction with PhSH.

In the sulfur derivatives \( \text{277} \)\(^644\), \( \text{278} \)\(^679\) and \( \text{283} \)\(^668\), the Sn atoms have a distorted TBP coordination with N and S in axial and two C atoms and another S atom or C atom and two other S atoms, respectively, in equatorial positions. The deviation from the ideal TBP

\(^a\)Toward the halide or sulfur atom.
\(^b\)Sn–S.
\(^c\)Sn–Cl.
\(^d\)Dimeric structure with an additional weak coordination to chlorine (3.58 Å).
structures is greater than in compounds of the type 239. In particular, the displacement of the tin atom from the equatorial plane in the direction of S axial is 0.26 Å for the dithia derivative 277 and 0.39 Å for the trithia derivative 283. Thus, in these compounds the intramolecular N → Sn coordination is weaker than that in 239, reflecting the poor Lewis acidity of a tin center containing the S-ligands.

2. Derivatives with bidentate C,O-chelating ligands and related compounds

a. Hydroxy, alkoxy and acyloxy groups as donor centers. These groups are effective intramolecular donor centers in mono-, di-, tri- and even tetra-organostannanes. The most favored and stable chelate ring size is the five-membered ring, but four-membered and six-membered chelate rings were also reported.

The α-D-allofuranose derivative 284, (Z)-2-methyl-3-triphenylstannyl-3-penten-1-ol 285, as well as a number of o-methoxyarylstanannanes including the o-anisylstannyl compounds 286 provide examples of particularly strained four-membered rings.

The vinylic compound 285 is a rare representative of tetraorganotin species with an O → Sn intramolecular interaction, as shown unambiguously by an X-ray diffraction
The O···Sn separation (3.012 Å) lies between the sum of van der Waals radii of Sn and O and the Sn−O covalent bond length (Table 1). Based on analogous data, a very weak O···Sn interaction leading to the formation of the four-membered ring can also be proposed in (2,3-O-isopropylidene-5-O-(triphenylmethyl)-α-D-ribofuranosyl)triphenylstannane (287) and 5-deoxy-1,2-O-isopropylidene-5-C-triphenylstannyl-α-L-xylofuranose (288), with O···Sn separations of 3.093 and 3.252 Å, respectively. However, intramolecular O···Sn separation up to 3.07 Å is usually considered as evidence for a similar interaction.

As a series of o-anisylstannanes, (o-An)$_n$SnX$_{4-n}$ ($n = 3, 4, X = Cl, Br; n = 2, X = Ph, Cl, Br; n = 1, X = Br) was most recently reported (289). The synthesis of (o-An)$_3$Sn (289) and (o-An)$_2$SnPh$_2$ (290) was provided by the reactions of the Grignard reagent from o-AnMgBr with SnCl$_4$ and Ph$_2$SnCl$_2$, respectively. Compounds (o-An)$_n$SnX$_{4-n}$ ($n \neq 4$) were obtained either from reactions of 289 with SnX$_4$ or X$_2$, or by halide exchange reactions.

The X-ray structural determinations of a number of o-methoxyarylstannanes, namely 289, 290, (o-An)$_3$SnI (291), (o-An)$_2$SnBr$_2$ (292a), (o-An)$_2$SnI$_2$ (292b) and o-AnSnBr$_3$ (293), as well as 5-Me-2-MeOC$_6$H$_4$SnCl$_3$ (294) and 2,6-(MeO)$_2$C$_6$H$_4$SnCl$_3$ (295), indicate only weak O···Sn interactions. The same conclusions were reached for 294, 295 and other 2-alkoxyaryltin trichlorides by $^{35}$Cl NQR studies.

The relative reactivities of aryl–tin bonds in (o-An)$_2$SnPh$_2$ (290) and (o-Tol)$_2$SnPh$_2$ toward iodine were determined. The lower [o-AnI]/PhI value (5.2 : 1) compared to the [o-Toll]/PhI ratio (68 : 5.1) is considered to indicate an enhanced reactivity of the Ph−Sn bond in 290, arising from the nucleophilic assistance by an o-anisyl group during the Ph−Sn bond cleavage.

Among the early reported saturated compounds containing a five- or six-membered chelate ring, representative examples for which the TBP structure in the solid state was established by X-ray crystallography are the γ-hydroxy and γ-methoxy tin derivatives, IPh$_2$Sn(CH$_2$)$_3$OH (296) and ClPh$_2$Sn(CH$_2$)$_3$OEt (297), the dimer 298 with four-membered SnO$_2$Sn cycle as well as the fluoride 299a and the chloride 299b.

The iodo compound 296 was prepared by the reaction of the tetraorganotin Ph$_3$Sn(CH$_2$)$_3$OH with I$_2$. The reaction proceeds ca 100 times faster than that with Ph$_3$Sn(CH$_2$)$_3$CH$_3$, both reactions leading to Ph−Sn bond cleavage. This difference in reactivities was considered to arise from the nucleophilic assistance afforded by the OH group in the first case.
n = 3, (b) n = 4, (c) n = 5), were obtained and their coordination behavior was investigated by X-ray diffraction, multinuclear NMR and semi-empirical AM1 quantum-chemical calculations. The routes to these functional organotin trichlorides include the formation of the corresponding organotricyclohexyltinyls by coupling of an organometal species with tricyclohexyltin chloride, by reaction of (tricyclohexylstannyl)lithium with an organic halide or by hydrostannation of alkenes. A subsequent treatment of organotricyclohexyltins with SnCl₄ yielded the corresponding organotin trichlorides. The latter were also used as key intermediates for the preparation of monoorgano- tin trialkoxides, which are precursors of organic—inorganic hybrid materials and clusters containing tin.

Recently, the structures of the dichloride Cl₂Sn[(CH₂)₃O(CH₂)₂OMe]₂ (302) and trichloride Cl₃Sn(H₂O)(CH₂)₃O(CH₂)₂OMe (303), both containing five-membered chelate rings but six-coordinated tin atoms, were established.

Carbohydrate tin derivatives have been produced in which the tin and carbohydrate units are directly linked via Sn–O bonds, as well as more indirectly via Sn–CH₂CH₂–C (sugar) bonds, and Sn–CH₂–O (sugar) bonds, and Sn–CH₂–C (sugar) units (for additional references see Reference). Most recently, the structure of furanoside was unambiguously determined by X-ray diffraction. Unlike in, the oxygen in the γ-alkoxide, the sulfur in thioethers ClPh-SnCH₂I, and IPh-SnCH₂I species with tricyclohexyltin chloride, by reaction of (tricyclohexylstannyl)lithium with an organometal toward I₂ indicate that at least the groups containing Sn separations are > 4.0 Å, while in, 6-O-benzylidene-3-deoxy-3-triphenyltin-α-D-altropyranose, even a weak intramolecular O → Sn interaction is absent (in the solid, the O • • • Sn separations are > 4.0 Å), while in, 4,6-O-benzylidene-3-deoxy-3-triphenyltin-α-D-altropyranose, a weak interaction can take place (the O • • • Sn separations are 3.24 and 3.35 Å, respectively).

Recently, a family of [α-D-galactopyranosyl]methyl]tin species Ph₅Sn(CH₂OR)₄–ₙ (305, n = 1–3), Ph₅Me₃–ₙSn(CH₂OR) (306, n = 0–3) and Bu₃SnCH₂OR were prepared from 1,2,3,4-di-O-isopropylidene-α-D-galactopyranose (ROH) and the iodomethyl tin compounds Ph₅Sn(CH₂I)₄–ₙ (n = 1–3), Ph₅Me₃–ₙSnCH₂I (n = 0–3) and Bu₃SnCH₂I. Several of the compounds 305 and 306 were transformed into iodoethers IPh₅Sn(CH₂OR)₃–ₙ (307) and IPh₅Me₂–ₙSnCH₂OR (308) by iododephenylation reactions with iodine. The rather high reactivities of 305 and 306 toward I₂ indicate that at least the groups containing oxygen within the carbohydrate unit(s) provide nucleophilic assistance in the cleavage step. X-ray diffraction shows the presence of the six-membered chelate ring in 307a (n = 1).

Like the oxygen in the γ-alkoxide, the sulfur in thioethers Cl₅SnS(CH₂OR)₄–ₙ and sulfide (Cl₅SnS(CH₂CH₂CH₂)₂S (309c) can act as an intramolecular donor. This was established by the X-ray studies of 309a and 309c and H-DNMR investigation of 309b.

A family of stannylvinyl compounds of the types (Z)-Ar₃–ₙXₙSnCH=CHC(OH)RR' (310, Ar = Ph, p-Tol; n = 0–2; X = Cl, Br, I, R, R' = Me, t-Bu, Ph, cycloalkyl), exhibiting a potential HO → Sn intramolecular interaction, were prepared and characterized by H, C, Sn NMR and Sn Mössbauer spectroscopy. Triaryltins 310 (n = 0) were synthesized by the addition of the corresponding triarylhalide to the appropriate terminal alkynyl. Subsequent reactions of the former with halogens in 1 : 1 or 1 : 2 molar ratio yield the corresponding mono- and dihalides, respectively. For some of these compounds, including the Ph₃Sn (310a–e) and (p-Tol)₃Sn (311) as well as IPh₅Sn (312), Cl(p-Tol)₂Sn (313) and Br₂(p-Tol)Sn (314) entities and also for Cl₅SnC[CH₂C(OH)PhCOPh]=CHCH₂COOEt (315), the structures in the solid state were established by X-ray crystallography. 315713
Polyfunctional ligand 316 (L-H, Scheme 14) contains two methoxy groups that are potentially capable of intramolecular coordination. A wide range of organotin compounds were prepared from the ligand, $n$-BuLi and Ph$_3$SnCl followed by reaction with formaldehyde and/or halogenation\textsuperscript{239,241}. These compounds, including tetraorganotins LSnPh$_3$ (317) and LCH$_2$SnPh$_3$ (318), triorganotin bromide LSnPh$_2$Br (319), diorganotin derivatives LSnPh$_2$X$_2$ (320) and LCH$_2$SnPh$_2$X$_2$ (322, 323), and monoorganotin trichlorides LSnCl$_3$ (324) and LCH$_2$SnCl$_3$ (325), are good models for comparison of the relative stability of five- and six-membered ring systems containing tin.

That the intramolecular O → Sn coordination in compounds 320 is relatively weak was also shown by replacing the intramolecularly coordinating oxygen by the external strong Lewis base Bu$_3$PO to yield 1 : 1 or 1 : 2 adducts\textsuperscript{239}. In the latter, the tin atom remains pentacoordinated and the added Lewis base displaces a halide group. The tendency to form the 1 : 2 adduct decreases in the sequence: I > Br > Cl. The Cl derivative forms no adduct.

A related series of heptacoordinate monoorganotin trichlorides 326a–d was prepared earlier by reducing tris(2,6-dimethoxyphenyl)methanol with the stannous halide in H$_2$SO$_4$ solution (equation 64)\textsuperscript{715}. X-ray crystallographic analysis of 326a–c revealed a capped octahedral arrangement at the central atom, with tin atoms covalently bonded to three halogens and the central carbon of the triarylmethyl unit and associated, in addition, with the three neighboring methoxy groups (anti to the halogens).

In view of the presence of tin atoms with a higher coordination number than five or six in 326a–c, these compounds are not discussed here in detail. Nevertheless, in contrast to two sequences of pentacoordinate triorganotin halides\textsuperscript{357,674} as well as to a sequence of pentacoordinate (O−Si)-chelate triorganosilicon halides\textsuperscript{502}, the O−Sn interaction in 326a–c is weakened on decreasing the Lewis acidity of the Sn center as the halogen substituents become less electronegative. An analogous trend was observed for the barriers $\Delta G^\ddagger$ to methoxy group site exchange in 326a–d, which decrease (being 19.8, 16.9, 15.5 and 14.1 kcal mol$^{-1}$, respectively) as the halogens change from F to I, i.e. in the order of decreasing electronegativity.

Tables 49 and 50 present some of the structural parameters pertinent to the geometry and hypervalency at tin for (O−Sn) chelates with hydroxy, alkoxy and acyloxy groups. These include the bond lengths of tin to the two apical ligands, the axial OsnAx angles, the displacement of the tin atom ($\Delta$Sn) from the central plane defined by three equatorial ligands and the bite angles of the chelate ligands. Changes in the latter parameter allow
SCHEME 14. Preparation of tin compounds containing substituted bis(2-methoxyphenyl)methyl moiety
one to discuss the chelate ring strains which generally lie in the range 49–52°, 66–73°
and 83–84° on going from four- to five- to six-membered rings, respectively. In particu-
lar, the deviation of the β-hydroxy derivative Ph₃SnC(CMe₂OH)=CHMe (285) from the
tetrahedral geometry is less marked than in the analogous γ-hydroxy compounds 310a–e,
where it is due to stronger intramolecular O → Sn interactions, of 2.73–2.77 Å as com-
pared with 3.01 Å in 285. This results from the presence of a less strained five-membered
ring in the latter compounds.

On going from tetraorgano- to triorganotin compounds the O → Sn interaction becomes
significantly stronger as a result of the higher Lewis acidity of the tin atom in the lat-
er compounds (e.g. compare the tetraorganotin derivatives 287 and 288 with the iodo
compound 284, and the γ-hydroxy compounds 310a–e with the halo compounds 312
and 313). In particular, the displacement of the Sn atom by 0.47 Å from the equato-
rial plane toward iodine in 284 represents a 39% distortion of its geometry toward a
TBP arrangement. Furthermore, the sum of the equatorial angles in 284 is 346.2° as
compared with the sum of an almost tetrahedral value of 329.8° for 288.

Comparisons of the O−Sn and Sn−I axial bonds in iodides 284, 296, 304 and 307a con-
taining 4-, 5-, 5- and 6-membered chelate rings, respectively, show that the longer O−Sn
bond lengths are generally associated with the shorter Sn−I distances. The strengthening
of the O → Sn interaction represented by the O−Sn distances and the ΔSn values follows
the order: 307a < 304 < 284 < 296.

The coordination behavior of alcohols 300a–c and acetates 301a–c depends on the
nature of a functional group, the length of the polymethylene chain between the tin
atom and the coordinating function, whether the compound is in the solid state or in
solution and the concentration in solution. In particular, based on multinuclear NMR
studies (selected data are given in Table 51), the C3 and C4 alcohols 300a and 300b
in the noncoordinating solvent, CD₂Cl₂, reveal a five- and six-membered ring structure,
respectively (Scheme 15), resulting from intramolecular HO → Sn coordination.¹¹⁹Sn
NMR spectroscopy resonances in trihalostannyl alcohols and esters are all shifted upward
with respect to nonfunctional alkyltin trichlorides. The effect is stronger with alcohols.

The NMR data for alcohols 300a–c in acetone-d₆ reveal a complex coordination behav-
ior involving five- and six-coordinated species in a fast equilibrium for which HO → Sn
and (CD₃)₂C=O → Sn interactions are in evidence. The crystal structure of alcohol
300c reveals a polymeric structure that arises from significant intermolecular HO → Sn
interactions of 2.356 Å. As a result, the tin atom is five-coordinate and exists in a distorted
TBP geometry with the oxygen and one of the chlorine atoms at the axial positions.

### SCHEME 15. Schematic representation of solid state and solution structure of alcohols 300a,b and acetates 301a,b

Unlike the alcohols 300a–c, the acetates 301a–c in C$_6$D$_6$ solution display fast equilibrium between a monomer with intramolecular coordination and an oligomer with intermolecular coordination$^{110}$. 301b$^{714}$ is a cyclodimer in the solid state (Scheme 15) with coordination from the carbonyl oxygen to the tin. During dynamic equilibrium in solution, the monomeric form of ester 301a with the methoxy oxygen coordinating to the tin is predominant, independent of the concentration. In contrast, for esters 301b and 301c the oligomeric form predominates increasingly upon concentration increase$^{716}$. Note that in the case of acetate Ph$_3$Sn$(\text{CH}_2)_3$OAc, the O−Sn interaction is absent in the solid state$^{717}$.

The chloride 299b and the related six-membered carboxylic tin species, in which an intramolecular O → Sn interaction stabilizes the 1,3-diaxial conformations$^{696}$, were discussed in detail in a review.$^{636}$ The corresponding trimethyltin derivatives in the absence of an O → Sn coordination exist predominantly as the 1,3-diequatorial conformers. Moreover, an X-ray structure determination of the fluoride 299a, the analogue of 299b, which
is monomeric in CHCl₃ solution and adopts a 1,3-diaxial conformation, reveals a fluorine-bridged polymeric structure containing a cyclohexyl ring with 1,3-diequatorial stannyl and benzyloxy groups.

An X-ray structure determination of IPhSn(CH₂OR)₂ 307a reveals that only one of the sugar moieties acts as a C₂O-bidentate ligand to form a six-membered chelate ring via the pyranose ring oxygen (Scheme 16)²⁶⁷. The tin center is five-coordinated and has a TBP geometry with I and O in the axial positions (Table 49). As indicated by the solid state and solution $\delta^{119}$Sn values (−177.8 and −130.7 ppm, respectively), the solid-state structure does not survive on dissolution. The $\delta^{119}$Sn and $^1J(^{119}\text{Sn}−^{13}\text{C})$ values for 305 and 306 are also as expected for a four-coordinate species, i.e. in solution the sugar units remain monodentate²⁶⁷.

As in alkoxide 297, in the sulfur derivatives ClPh₂Sn(CH₂)₃Stol-p (309)⁷⁰⁴ and (ClMe₂SnCH₂CH₂CH₂)₂S (328)⁷⁰⁵, the tin atom has a distorted TBP coordination geometry, with the S and Cl atoms in the axial positions (Table 49). The S−Sn distances
of 3.19 Å for 309 and 3.10 and 3.12 Å for 328 lie between the sum of the covalent radii for Sn and S (2.44 Å) and the sum of their van der Waals radii (3.9 Å). The weaker S–Sn interaction in 309 than in 328 reflects the weaker donor ability of alkyl aryl sulfides compared with dialkyl sulfides. According to Dräger535, the formal bond order for the S → Sn coordination bond in 309 is 0.22, while an analogous calculation for ClMe2Sn(CH3)2PPhBu−r294 provides a value of 0.44 for the P → Sn coordination bond compared to values of 0.6 to 0.7 for triorganotin halide complexes involving an intra- or intermolecular N → Sn or O → Sn coordination. The displacement of the Sn atom from the equatorial plane in the direction away from S is 0.27 Å, which represents a 63% distortion toward a TBP array. This distortion is slightly greater as compared with 297 (Table 49). By contrast, in triphenyl-(2-(p-tolylthio)ethyl)tin718 and (4-chloro-3-(2-nitrophenylthio)butyl)triphenylstannane719, intramolecular S → Sn interactions are absent, at an S···Sn separation of about 4.8 Å.

In the crystals of triarylstannylvinyl compounds 310a–c and 311 the tin atom exhibits a distorted tetrahedral SnC₄ geometry toward TBP as a consequence of a close intramolecular contact with the hydroxyl oxygen atom of 2.73–2.77 Å. A distorted TBP geometry is found in mono- and dihalides 312–314, in which significant O → Sn interactions are noted (2.41–2.50 Å) (Table 49). In particular, the O–Sn bond in 310c is shorter than that in 311, and the O → Sn interaction in 313 is significantly stronger than those in 314 and especially in 312, in parallel with the Lewis acidity of the Sn atoms in these compounds. Thus, the X-ray crystallographic data allow one to place the corresponding tin entities in the following order of their Lewis acidity: (p-Tol)3Sn < Ph3Sn ≪ IPh2Sn < Br2(p-Tol)Sn < Cl(p-Tol)2Sn.

The solution ¹H, ¹³C and ¹¹⁹Sn NMR spectral data for all compounds of the types 310 and 311 are consistent with their expected more or less distorted tetrahedral or TBP structures and with the available X-ray data discussed above711. The systematic high-frequency shift of the observed ¹¹⁹Sn resonance for all p-tolyl compounds relative to that for the corresponding phenyl compounds is noteworthy. In addition, the ¹J(¹³C–¹¹⁹Sn) coupling constants decrease to a comparable extent in the sequence Cl > Br > I for both mono- and dihalides, reflecting the decreasing apicophilicity on going from chloride to iodide.

The intramolecular O···Sn separations in (o-An)ₙSnX₄₋ₙ (n = 1–4, X = Br, I) are in the range 2.8–3.1 Å and generally decrease with increasing Lewis acidity of the tin center. The consequences of the O···Sn interactions are an increase in the coordination number of tin in the O-methoxyarylstannanes and distortions of their geometries from tetrahedral toward TBP or octahedral (Table 50). However, given the small C_pseSnO(Me) angles of about 50°, the geometries are far removed from the ideal TBP or octahedral geometries. In particular, the ‘axial-Sn-axial’ angles in O-AnSnBr₃ (293)686, 5-Me-2-MeOC₆H₃SnCl₃ (294)691 and 2,6-(MeO)₂C₆H₃SnCl₃ (295)692 of 162.1, 161.8 and 168.7°, respectively, are somewhat removed from the ideal 180° expected for a TBP structure. Furthermore, the sum of the three ‘equatorial angles’ of 333.6° in 293 is closer to the value expected for a tetrahedral (328.5°) than for a TBP geometry (360°)686.

A detailed analysis of the changes in the exocyclic angles α, β, γ and δ of the o-anisylstannyl fragment 286, as indications of the O···Sn interactions in the o-anisylstannanes, is given elsewhere686. The most significant variations are for the angle β. The decreasing value of β, i.e. as the Sn center progressively leans toward the oxygen, indicates a more positive O–Sn interaction (Table 50).

X-ray crystallography reveals distorted TBP geometries for the diorganotin derivatives 320a–c and 321, owing to the presence of significant O → Sn interactions that are in the range from 2.56 Å for 320a to 2.99 Å for 321. One of the oxygen atoms and one of the halogen or SPh moieties define the axial angle in this description, and the tin atom lies
bonyl group, a family of so-called ‘estertin’ compounds, i.e. species containing the bonyl group, a family of so-called ‘estertin’ compounds, i.e. species containing the

LSnPhI\(_2\) \((317, 318)\) NMR data (Table 52), compounds LSnPhBr\(_2\) \((320a)\) and LSnPhCl\(_2\) \((320b)\) geometry is found in the tetraorganotin derivative \(317\), with O···Sn separations of 3.02 and 4.40 Å as compared to the sum of the van der Waals radii of 3.5 Å for these atoms and the ΔSn value of 0.65 Å. For \((\omega\text{-AnCH}_2\text{)}\text{I}_4\) Sn \((327)\) (Table 50) a significant distortion of the tetrahedral coordination around the tin toward the TBP geometry does not take place (the O···Sn separation is 3.241 Å and ΔSn = 0.72 Å)\(^{687}\).

Thus, the magnitudes of the O→Sn interactions correlate with the Lewis acidity of the tin atoms in the X\(_2\)PhSn entities, i.e. Cl\(_2\)PhSn > Br\(_2\)PhSn > I\(_2\)PhSn > (PhS)\(_2\)PhSn\(^{239}\).

NMR spectroscopy indicates a similar correlation in solution. As evidenced by \(^{119}\)Sn NMR data (Table 52), compounds \(317, 318\) and \(321\) are essentially four-coordinate between \(+30\) and \(-100^\circ\)C. In compounds \(320a\)–\(c\), \(322, 323a, 323b\) and \(325\) both four- and five-coordinate tin species exist simultaneously at low temperature. At higher temperatures, an average of these two coordination states is observed.

The positions of these equilibria are affected not only by the Lewis acidity at tin, but also by the ring size. Unlike the five-membered ring analogues \(320a, 320b\) and \(324\), equilibria involving compounds \(322, 323a, 323b\) and \(325\) containing six-membered rings are fast on the NMR time scale at all temperatures measured and only averaged signals were observed. Finally, note that for neither series (L or CH\(_2\)L, Scheme 14) was there any evidence for intramolecular coordination of both methoxy groups to tin\(^{239}\).

\textit{b. Carbonyl and related groups as donor centers.} Among compounds with a carbonyl group, a family of so-called ‘estertin’ compounds, i.e. species containing the

\(^{a}\)In toluene.
ROOCCH₂CH₂Sn moiety, has been most extensively studied. They are of particular interest due to both their use as precursors of potentially valuable organotin-based polyvinyl chloride stabilizers and the ability of the ROOCCH₂CH₂ unit to act as a chelating ligand by utilizing the carbonyl oxygen as an additional donor center. The main types of estertin compounds which are presented in Scheme 17 include halides (pseudohalides), namely trichlorides 329a, 329b, 330 and 331, adducts of trichlorides with O-donors 332a, 332b, 332c and 332d, the phenol and β-naphthol derivatives, 333 and 334, the itaconic species Cl₂SnCH₂CH(COOMe)₂CH₂COOME (335), dimeric hydroxide 336 with hydroxo-bridging, dichlorides 337a and 337b, with potentially bidentate dimethylthiocarbamate ligand (S₂CNMe₂ = DMT), dihalides (dipseudohalides) X₂Sn[CH₂CH₂COOME]₂ (338a–c X = Cl₇₂₂,₇₃₂, I₃₄⁷ and NCS₃₄⁷), including mixed chloride–bromide ClBrSn(CH₂CH₂COOME)₂ (339)₃₄⁷, the N-acetylaminomalonial ester derivative Br₂MeSnCH₂C(COOEt)₂NHCOMe (340), the dichloride and diisothiocyanate X₂Sn[HB(Pz)₃] (CH₂)₂COOME (341a, X = Cl, and 341b, X = NCS) where HB(Pz)₃ is the tridentate hydrido-tris(pyrazol-1-ylborato) ligand, as well as mono-halides, including iodide IP₇₂₃H₂Sn(CH₂)₂COOME (342)₇₃₅, the alane derivatives Cl₂SnCH₂CH(N=CPh₂)COOEt (343)₇₅₆ and Cl₂Ph₂SnCH₂CH(COOEt)NHCOMe (344)₇₃₇, the monochlorohalides ClSn(DMTC)((CH₂)₂COOME)₂ (345)₇₃₈ and ClₙSn(DMTC)₂(CH₂)₂COOME (346)₇₃₉ with DMTC ligand, ClₙSn[H₂B(Pz)₂](CH₂)₂COOME (347) with the bidentate dihydro-bis(pyrazol-1-ylborato) (BTB) ligand, the 8-hydroxyquinoline (8-HO-Qu) derivative ClₙSn(8-O-Qu)(CH₂)₂COOME (348)₇₄⁰ and the imine ClₙSn(L)(CH₂)₃COOME (349) containing the negative bivalent tridentate O,N,O-coordinating ligand L (LH₂ = N-(2-hydroxyphenyl)salicylaldimine)₇₄¹. Furthermore, the unsaturated species 350a–d have been described. In addition to the structures shown, in part, in scheme 17, hexa-coordinated species are given in Section X.B. The structures were established in these cases by X-ray crystallography. The structures of other representatives of estertin and related compounds with halide as a ligand were suggested only on the basis of spectral data. Estertins, in particular, adducts of trichlorides with O-donors and the 1 : 1 adducts with bidentate donors, have been prepared. Additionally, the reaction of trichlorides 329a and 335 with the DMTC ligand (taken as Me₂NCSNa·2H₂O) in appropriate molar ratios affording products of the type Cl₃–ₙ(DMT)nSn(CH₂)₂COOME (n = 1–3) including the dichloride 337a or 337b were carried out. The reaction of 337a with N-(2-hydroxyphenyl)salicylaldimine...
in the presence of Et$_3$N gave the monochloride 349. The latter reacted with the various alcohols ROH (e.g. R = Et, Pr, i-Pr, All, ClCH$_2$CH$_2$) yielding the appropriate transesterification products. The treatment of esterin trichloride 335 with 1,2-dianilinoethane gave a partial hydrolysis product 336 instead of the amine adduct of esterin $^{182}$.

SCHEME 17. Estertin compounds containing halide or pseudohalide as ligand
Reaction of dithiocarbamatoestertin dichloride 337a with sodium sulfide resulted in the dimeric species 351, whereas the cognate reaction of dichloride 338a gave the trimeric complex 352.

According to equation 20 (Section IV.B.2.b), the reaction of 329a with the appropriate zinc salt gave the anionic derivatives 111a–c, 112c and 112d.

Another synthetic way to organotins involves the halodemetalation reactions of the related tetraorganotin derivatives by the action of halogens, Me2SnCl2 or SnCl4 as realized in the case of halides 330–345, 342, 735 and 350b–d. Treatment of 350d with potassium fluoride in acetone afforded fluoride 350a.

Transesterification reactions of 2-alkoxycarbonylethyltin trichlorides and their adducts with neutral donors proceed readily. This is attributed to the intramolecular Lewis catalysis by the electrophilic SnCl group owing to the coordination of the ester carbonyl group to the tin atom, C=O → Sn, which decreases the electronic density at the carbonyl carbon atom.

Details of the structures of a variety of estertin compounds in the solid state are given in Table 53. Complexes with either mono- or bidentate ROOCCH2CH2 groups are characterized by a ν(C=O) value between those for a coordinated and noncoordinated ester group (1670–1680 and 1730–1740 cm⁻¹, respectively). With the appropriate number of donor atoms, estertins exhibit a tendency to become six-coordinated as evident, in part, in the examples of adducts 332a–d and on going from trichlorides 329a and 329b to dichlorides 338a–d. In the cases of 341a and 341b, C6H5Sn(DMT)2(OMe)(CH2)2 (345) and Sn(DMT)2(CH2CH2COOMe)2 (356), the coordination number becomes even higher at seven if weak interactions are also considered. This value is somewhat outside the limit normally taken for hypervalent O–Sn bonding (ca 2.9–3.0 Å). Without regard for such interactions, the tin atom is tetracoordinate in trimer 352 and five-coordinate in dimer 351.

In the solid state, the Sn atom in the itaconic species 335 adopts a distorted octahedral arrangement with the five- and six-membered fused rings via the two carbonyl oxygen-to-tin coordinations. On the basis of IR and multinuclear NMR spectroscopy data it was suggested that one carbonyl group presumably involved in the six-membered chelate is released from the tin atom, which results in a five-coordinate tin atom in solution in both coordinating and noncoordinating solvents.

The bite angle of the RO2CCH2CH2 group in estertins correlates with the O–Sn bond length. The correlation applies not only for complexes in which the estertin group is clearly chelating, but for compounds with the O···Sn separation of 3.0–4.0 Å, too. Using this criterion, a very weak but definite ester-to-tin interaction for estertins with the O–Sn distance up to ca 4.0 Å can be proposed.

The crystal structure determinations and spectral data show that the carbonyl oxygen in the 1 : 1 adducts of trichlorides of the type 329 (R = Alk, Ar) with monodentate donors like pyridine is coordinated intramolecularly to tin. However, the intramolecular coordination can be broken in the 1 : 2 adducts with monodentate donors and with 1 : 1 bidentate donors like bipyridine.

Some crystallographic data for estertins containing pentacoordinate tin atom owing to O–Sn interaction are collected in Table 54. In these compounds the tin atom has a near TBP coordination geometry with the carbon atom and the two chlorines or the three carbon atoms at equatorial positions and the halogen and oxygen atoms at axial sites. In general, the goodness of a TBP array at tin is defined by the deviation of the Sn from the equatorial plane toward the halide atom (∆Sn), and by the difference (∆Σ(θ)) between the sums of the equatorial and axial angles. For the two series of chelates, trichlorides 329a–c and monohalides 350a–d, the values are rather close (∆Sn, ca 0.25–0.30 Å; ∆Σ(θ), 55–66°). In 350a–d, the lengthening of the Sn–Hal bond in relation to the

Single bond distances increases in the order: F ≪ Cl < Br < I. The coordinating O → Sn distance is in the order: F > Cl = Br > I with the shortest O−Sn distances for 350d. A detailed analysis of the geometrical variables in 350a–d suggests that pπ−dπ back donation from the halogen to the tin in 350a–d could invert the order of tin Lewis acidities expected on the grounds of simple halogen electronegativity. 350e is the first tetraorganotin compound with a coordinative tin–oxygen bond for which the structure was unambiguously established by X-ray crystallography.  

Comparison of the O → Sn bond lengths in trichlorides 329a and 330 reveals a longer coordinate bond in 330 (2.347 and 2.405 Å, respectively). This indicates a stronger coordination in the five-membered chelate 329a than in the six-membered chelate ring of 330. From the formation constants for adducts of 329a and 330 with pyridine, aniline and quinoline it is seen that this is also true in solution.  

The ¹¹⁹Sn NMR resonances of 330a–d exhibit an upfield shift about 100 ppm with regard to values expected for uncoordinated halides, indicating pentacoordination of the tin atom in solution.  

Comparison of the intramolecular coordination behaviors of (PhC≡C)₃Sn(CH₂)₂ COOMe (358) and 329a was carried out, using multinuclear NMR, including ¹H−¹¹⁹Sn-HMQC spectroscopy. While 329a exhibits an intramolecular carbonyl...

oxygen-to-tin coordination in solution, unlike acetate 301a, which coordinates through the alkoxy oxygen (see above), no firm evidence has been obtained for the existence of such an interaction in 358. This is ascribed to the lower electronegativity of an alkynyl group than of a chlorine atom.

A series of compounds (Bu$_3$Sn)$_2$CHCHRCO$_2$Me (R = CH$_2$CH=CH$_2$, CH$_2$Ph, CH$_2$NMe$_2$) was obtained by reaction of the precursor with R = H with LiNPr$_2$-$i$, followed by treatment of the corresponding halide RBr or RI$^{756}$. The conformational dependence for these species on the temperature and concentration was studied by means of Karplus-type dihedral angle relations for $^3J(^{119}$Sn–$^{13}$C) couplings. The results point toward a dominant conformation in which a very weak carbonyl oxygen-to-tin interaction is possible.

The reaction of ClCH$_2$SnMe$_2$Cl with N-TMS amides and lactams requires more drastic conditions (o-xylene, 80–100 °C) than the analogous reactions of ClCH$_2$SiMe$_2$Cl and ClCH$_2$GeMe$_2$Cl (Section VI.A.1.c) and, in general, leads to a mixture of the O- and N-alkylation products$^{484,494,757}$. A multistage reaction scheme established by NMR monitoring includes the transmetallation products 359 followed by subsequent formation of O-stannylmethyl and finally N-stannylmethyl derivatives, 360 and 361, respectively (Scheme 18).

Chlorides 361b and 361c were isolated. The pentacoordination of the tin in 360a–c and 361a–c was confirmed by significant upfield shifts of the signals in the NMR $^{119}$Sn spectra (−73.5 ppm for 360a–c and −40.6, −42.8 and −35.3 ppm for 361a–c, respectively) in comparison to the CICH$_2$SnMe$_2$Cl signal (112.3 ppm).
SCHEME 18. Reaction of ClCH₂SnMe₂Cl with trimethylsilylated amides and lactams

An X-ray diffraction of 361b revealed a TBP arrangement at the tin center, with the axial oxygen and halogen atoms. Comparison with the corresponding Ge and Si analogues 144c and Si-101b suggests that the geometry of the hypervalent OMC₃Cl moiety retains a TBP shape but changes markedly in the series Si-101b → 144c → 101b. Both components of the hypervalent O−M−Cl bond increase with the increasing size of the M atom (Table 55), although in a different way: the O−M distance has a larger leap on Si and Ge interchange, while the M−Cl distance is more sensitive to the Ge by Sn replacement. The lengthening of the M−Cl bond in relation to the single bond distances increases on going from Sn to Ge to Si.

The general state of the OMC₃Cl fragment may be defined by the parameters ΔM and ΔΩ, defined above. These two parameters indicate that the deviation from the ideal TBP increases along the row of Si → Ge → Sn, more significantly so on the Si → Ge substitution.

Like the reaction of ClCH₂SnMe₂Cl with N-TMS amides and lactams (Scheme 18), its reaction with O-TMS N-acetylacetamide yields a mixture of the O-alkylation (not

a Lengthening of the bond distance in relation to the single bond.

b Displacement of the central atom from the equatorial plane.

c Ω is a solid angle formed by three equatorial bonds of the central atom (see text). L^n is the n-membered lactamomethyl ligand with R^n = MeCON(CH(Ph)Me)CH₂.
shown) and N-alkylation products (362). In the latter the degenerate 1,5-migration of the ClMe₂Sn group, in which the tin atom is a constituent of the coordinate bond, takes place between two carbonyl oxygen atoms (equation 65) with an activation free energy $\Delta G^\#$ of 11.5 kcal mol$^{-1}$.

$$\text{(362)}$$

Based on the IR, $^{119}$Sn NMR and $^{119}$Sn Mössbauer spectroscopy, the tin atom in tetraorganotin derivative 363a is suggested to be tetracoordinate, but it is pentacoordinate both in the iodide 363b due to the O → Sn interaction and in the dithiocarbamate 363c due to the bidentate mode of the thiocarbamate ligand.

$$\text{(363a)} \quad X = \text{Ph} \quad \text{(363b)} \quad X = \text{I} \quad \text{(363c)} \quad X = \text{S}_2\text{CNMe}_2$$

Ketoorganostannanes $\text{R}_3\text{Sn}(\text{CH}_2)_n\text{COR}'$ and ketoorganohalostannanes $\text{ClR}_2\text{Sn}(\text{CH}_2)_n\text{COR}'$ ($n = 2, 3$; $R, R' = \text{Me, Ph}$) have been known for a long time but have been less extensively investigated, especially in regard to their coordination chemistry. Based on the IR, $^1\text{H}$ and $^{13}\text{C}$ NMR and $^{119}$Sn Mössbauer spectroscopy, a TBP structure with intramolecular O → Sn coordination for chlorides 364a, 364b and 365a–c was suggested. This coordination is relatively weak as shown by replacement of the intramolecular coordinating oxygen atom by external ligands like pyridine. As indicated by IR spectroscopy, diketone ClMe₂SnCH₂CH[COPh]₂ contains one intramolecularly tin-coordinated carbonyl group resulting in pentacoordinate tin, whereas the other carbonyl remains uncoordinated in the solid state ($\nu(\text{C} = \text{O}) = 1627$ and 1670 cm$^{-1}$, respectively).

Among organotin species incorporating (C=)O → Sn coordination, compounds including an (X=)O → Sn moiety ($X = \text{heteroatom, P or S}$) have been also reported. According to NMR data, a tetrahedral geometry at tin in solution is suggested for
2-Me₃SnFcCH₂POPh₂ (231). The tetraorganotin compounds 366 and 367 were recently prepared (equation 66).

(367)

X-ray determinations show that the tin centers in these compounds have strongly distorted TBP geometries with weak O → Sn interactions of 2.80 and 2.79 Å, respectively. These are of the same order of magnitude as those in tetraorganostannanes 91, 285, 310a and 310b discussed earlier (see Tables 49 and 53).

The earlier examples of the five-membered chelate ring with triorganotin moiety include phosphoryl derivatives, e.g. chlorides 368a–d and 369a-d, the ferrocenyl species 269b (Section VII.A.1.c), the bromide BrMe₂SnCH₂CH₂POPhBu-t (370), ditin species(ClMe₂SnCH₂CH₂)₂POPh (371) as well as the fluoride 372a and the S and Se analogues of phosphine oxide, bromide 372b and chloride 372c. Bromides 369b and 369c were recently obtained by the reaction of tetraorganotin compounds 366 and 367 with 1 or 2 equivalents of bromine. Bromide 369c was also synthesized by treatment of 367 with an excess of Me₃SiBr.

Starting from tetraorganotin compounds Me₃SnCH₂CH(X=O)Y=O and HCl or Me₂SnCl₂, a family of 2,2-difunctional triorganotin chlorides of the type ClMe₂SnCH₂CH(X=O)Y=O (373, X=O, Y=O = P(O)R₂, COR, R = Ph, OEt, OPr-i) was recently prepared.

Crystal studies of 369a-d, 369b, 370, 371, 372a, 372b, 372c reveal a distorted TBP ligand arrangement at the tin atom owing to the intramolecular...

\]

and the three carbon atoms define the equatorial plane. Selected structural data pertinent to the TBP structures are collected in Table 56.

In tetraorganotin compounds 366 and 367 and the bromide 369b the \( \text{P}=\text{O} \) groups are directed toward the tin atoms, resulting in real structures along the T → TBP path\textsuperscript{762}. The position along this path is given by the differences in the sum of the equatorial and axial angles (90° for ideal TBP, 0° for ideal T). It amounts to 36.8° for 366, 34.3 for 367 and 65.9° (average) for 369b.

The crystal structure determinations of difunctional 373a\textsuperscript{770} and 373b\textsuperscript{747}, IR spectroscopic data and NMR studies\textsuperscript{747} show that one of the two functional groups is intramolecularly coordinated to tin, resulting in its pentacoordination, whereas the other donor group remains uncoordinated in the solid state. The structure of 373a reveals that the POPh\textsubscript{2} group with the higher donor ability is coordinated at the tin atom and the PO(OPr-i)\textsubscript{2} group remains uncoordinated. Crystal structure determinations and spectroscopic data assign the following sequence of increasing donor strength for the corresponding functional group both in the solid state and in solution: COPr-i < COPh < PO(OPr-i)\textsubscript{2} < PO(OPr-i)Ph < POPh\textsubscript{2}\textsuperscript{747}.

The triorganotin compound 374 has been prepared by reaction of new functional Grignard reagent (EtO)\textsubscript{2}POCH\textsubscript{2}SiMe\textsubscript{2}CH\textsubscript{2}MgCl with Me\textsubscript{3}SnCl and subsequent treatment with Me\textsubscript{2}SnCl\textsubscript{2}\textsuperscript{771}. The crystal structure reveals a nearly ideal TBP coordination of the tin atom that results from a six-membered chelate ring having a chair conformation.

† Toward the halide atom.
‖ Hypervalent fragment Hal−Sn(2)···Halbr.
§ Only the POPh₂ group is coordinated.
¶ Dimeric structure with six-coordinate tin atoms.
∥ Both P=O groups are coordinated.
†† Away from Halbr.
‡‡ An additional intermolecular Hal···Sn interaction.
As shown by DNMR investigations, a ligand exchange process occurs in solution of both the monofunctional chlorides \(368a-d\) and the difunctional halides \(373a\) and \(373b\). The barrier for \(368a-d\) decreases dramatically on lowering the donor strength of the P\(=\)O group, while the configurational stability of \(373a\) and \(373b\) increases with decreasing the donor strength of the functional groups X\(=\)O and Y\(=\)O. For compounds \(368a-d\) the hexacoordinated intermediates \(375\) are suggested as transition states in donor solvents (D), whereas in apolar solvents the process is expected to proceed via dimeric species like \(376\). In the case of the halides \(373\), it is suggested that the uncoordinated donor group induces a ligand exchange in a neighboring molecule by intermolecular O\(\cdots\)Sn interactions via hexacoordinated dimeric species of the type \(377\).

Unlike triorganotin phosphoryl compounds, the alkyldihalostannylibisphosphonates \(X_2RSnCH_2CH[PO(OPr-i)_2]_2\) (X = Cl, Br; R = Me, Bu-t) exist as dimers in the solid state with hexacoordinated tin, resulting from intramolecular P\(=\)O \(\rightarrow\) Sn coordination of one P=O group as well as an intermolecular P=O \(\rightarrow\) Sn interaction of the second P=O group with the tin atom of a neighboring molecule, as in ClBrMeSnCH_2CH[PO(OPr-i)_2]_2 (378). In solution, a concentration and temperature dependent equilibrium takes place between dimeric and monomeric species\(^{141, 775}\). However, if the hydrogen of the central CH group is substituted by a methyl group, as in Br_2MeSnCH_2C(Me)[PO(OPr-i)_2]_2 (379), both P=O groups act as a tridentate ligand in the octahedral ligand array at the Sn atom and the structure remains unchanged in solution\(^{772}\).
Examples of organotin complexes incorporating S=O → Sn coordination are the ditin sulfoxides, 380a and 380b, and 381a and 381b, as well as sulfone 382. Based on the X-ray studies (Table 56) due to O → Sn interaction all compounds contain a pentacoordinate tin atom in a six-membered chelate ring with the metal atom having a near-TBP coordination geometry. The second Sn atom in chloro and bromo 380 and 381 is also pentacoordinated by virtue of a weak intramolecular Hal···Sn interaction due to the Sn···Hal···Sn bridging. Moreover, both coordination sites in 381a and 381b are distorted owing to a weak additional interaction through halide bridging between two adjacent binuclear units.

In contrast, an intramolecular S=O → Sn interaction is absent in tetraorganotin compounds Ph3Sn(CH2)ₙTos-p (n = 2–4). Based on ¹H, ¹³C and ¹¹⁹Sn NMR studies it was suggested that the O of the sulfoxide group undergoes a rapid coordinative exchange between the two tin atoms in each of the compounds 380 and 381 in solution.

3. Monocyclic derivatives with other bidentate chelating ligands

Although organotin compounds with monoanionic C,N- and C,O-chelating ligands were most extensively studied in relation to hypervalency, complexes containing other monoanionic bidentate X,D-chelating ligands (X, D = N, O, S) have also been reported. Among them, the β-diketones, carboxylate and dithiocarbamate (DTC) derivatives are most widely known.

The organotin carboxylates may adopt a variety of structural modes depending on the nature of the organic substituent on the tin atom and/or the carboxylate
In the crystalline state, triorganotin carboxylates generally adopt either a polymeric structure with a five-coordinated tin atom (type 383) or a monomeric structure varying from a purely tetrahedral four-coordinate geometry (type 384) to a similar one with a weak additional intramolecular coordination from the carbonyl oxygen to the tin atom (type 385). The polymeric structure 383 is especially common in the crystalline state. However, sterically demanding groups apparently favor a monomeric structure (384 or 385). Furthermore, the electronegativity difference between the organic groups R and the carboxylate moiety plays an important role.

Some of the organotin DTC complexes are discussed above (see Table 53 and compounds 264a and 266b, Section VII.A.1.c). For the organotin dithiocarbamates, it has been found that small variations in tin-bound or nitrogen-bound organic substituents may lead to very different coordination geometries about the tin. In particular, for derivatives of the type ClPh₂SnDTC the complexes contain essentially four-coordinate tin, but with wide variations from the normal tetrahedral environment. For chlorides ClR₂SnDTC (R = Alk, Ph), the DTC ligand is generally bonded to the tin atom in an anisobidentate manner.

¹¹⁹Sn NMR spectroscopy is very useful for elucidating the nature of the coordination in DTC complexes of tin. There is an approximately linear dependence of the δ(¹¹⁹Sn) values on the coordination number of the complexes. Thus, the δ(¹¹⁹Sn) values are between −150 and −250 ppm in pentacoordinate, between −300 and −500 ppm in hexacoordinate and between −700 and −800 ppm in heptacoordinate compounds. Based on ¹¹⁹Sn and ¹⁵N NMR data, an intramolecular N → Sn coordination was detected analogously in the cases of N,N-TMS(trimethylstannyl)-2-aminopyridine, N,N-TMS(trimethylstannyl)-N-TMS-2,6-diaminopyridine and 2-[N,N-bis(trimethylstannyl)amino]pyridine.

Most recently, the hydroxylamine derivative Me₃SnONMe₂ (386) was found to be an exotic example of a triorganotin compound containing a three-membered chelate ring resulting from intramolecular coordination. A secondary interaction between the tin and nitrogen atoms has been detected on the basis of a gas-phase structure determination by electron diffraction, an X-ray crystallographic study in the solid and ab initio calculations (MP2/DZ(P)), with O···Sn distances of 2.731, 2.745 and 2.661 Å, respectively. In the crystal, the coordination sphere of tin is further enlarged by an intermolecular Sn···O contact (2.998 Å) and a 4 + 2 coordination geometry is achieved, as deduced from the distorted TBP with one of the axial substituents replaced by the two weak contacts. It is noteworthy that 386 is the first partially hypercoordinate tin compound studied in the gas phase.
Some crystallographic data for selected cases of organotin and organolead complexes of the type $\text{387}$ containing monoanionic X,D-chelating ligands ($X, D = N, O, S$) are given in Table 57; their structures are given in Chart 1. These compounds, however, are beyond the scope of this review and will not be discussed in detail.

### Table 57. Some structural parameters for selected tin and lead pentacoordinate compounds of the type $\text{387}$ containing a DMC$_2$XY moiety ($M = \text{Sn}, \text{Pb}$) with monoanionic X,D-chelating ligand

### B. Bicyclic Complexes

#### 1. Stannocanes

Among the numerous pentacoordinated organotin derivatives reported so far, stannocanes are the most systematically studied. The three main types of stannocanes are 4,6-dioxastannocanes (388–390), 4,6-dithiastannocanes (391–393) and 4,6-dicapastannocanes (394–396). Depending on the donor (NR, O, S), each type may be further subdivided into groups of compounds with identical or different substituents (X and Y) at the tin atom.

Different stannocanes may be prepared by the reaction of organotin halides<sup>817,818</sup> or SnHal<sub>4</sub><sup>819</sup> with a suspension of disodium diolate in THF and disodium dithiolate in toluene and ethanol or with free diethiols in CHCl<sub>3</sub>. These reactions yield...
CHART 1. The structures of organotin and organolead complexes of the type containing monoanionic X,D-chelating ligands (X, D = N, O, S)
symmetrically \((X = Y)\) and unsymmetrically \((X \neq Y)\) substituted 1-aza-4,6-dioxo- and -4,6-dithiastannocanes (equation 67a,b)\(^{820}\). The symmetrically substituted compounds may be also synthesized from diorganotin dialkoxides or oxides in the presence of KOH as catalyst (equation 67c,d)\(^{817,820}\).

1-Oxa- and 1-thia-4,6-dioxo- and -4,6-dithiastannocanes \(389, 390, 392\) and \(393\) were prepared by similar methods from the respective organotin halides or \(\text{SnHal}_4\) and diolate or dithiolate salts \(\text{D(CH}_2\text{CH}_2\text{ZNa})_2\) \((\text{D} = \text{O}; \text{Z} = \text{O}, \text{S})^ {818-820}\).

High yields in some of these reactions indicate the formation of pentacoordinate tin intermediates whose structures may resemble \(397^ {820,821}\).

Some special types of stannocanes were prepared using the same common methods of stannocane framework generation. Similar to equation 67c,d, the reaction of
dialkyltin oxides or dialkyltin alkoxides with N-methyliminodiacetic acid gives 3,7-stannocanediones 398. Reaction of [CH₂(PhSnO)₂]ₙ with dithiol MeN(CH₂CH₂SH)₂ yields bis-stannocane 399. Separation of the mixture of oligomeric products from the reaction of [(t-Bu)₂Sn(OMe)₂] with RP(CH₂CH₂SH)₂ gave 16-membered Sn,P-heterocycles [(t-Bu)₂Sn(SCH₂CH₂PR]₂ 400 (R = Me, Ph) instead of the expected 8-membered derivatives 823.

Transannular interactions in compounds 400 and in the products of their reaction with sulfur or selenium [(t-Bu)₂Sn(SCH₂CH₂P(X)R]₂ 401 (X = S, Se) are absent. For 401 (R = Ph, X = S) this was confirmed by an X-ray study. However, according to NMR data (δ(¹¹⁹Sn) = −183.0 ppm, δ(³¹P) = −40.5 ppm, Jₘₙ₋ₚ = 1185 Hz), such interaction takes place in phosphastannocane ClPhSn(SCH₂CH₂)₂PPh (402), which was prepared from PhSnCl₃ and (NaSCH₂CH₂)₂PPh, similarly to the route in equation 67b 825.
Other suitable starting materials for stannocanes are eight-membered derivatives of tin(II), which may be readily transformed to the corresponding tin(IV) compounds according to equation 68.

\[
\text{Sn}(\text{ZCH}_2\text{CH}_2)_2\text{D} + \text{X}^- \rightarrow \text{X}_2\text{Sn}(\text{ZCH}_2\text{CH}_2)_2\text{D}
\]

\[\text{D} = \text{NR}, \text{PR}, \text{O}, \text{S}; \text{X} = \text{Cl, Br}, \text{I}, \text{SPh, OCOPh}; \text{Z} = \text{O, S} \quad (68)\]

Equation 69 illustrates the formation of spirocyclic ‘double stannocanes’ 403–405 from Sn(II) derivatives.

\[
\text{Sn(SCH}_2\text{CH}_2)_2\text{D} + (\text{HSCH}_2\text{CH}_2)_2\text{D} \rightarrow \text{H}_2\text{Sn}(\text{SCH}_2\text{CH}_2)_2\text{D}
\]

\[\text{D} = \text{NMe}(404) \quad \text{D} = \text{O}(405) \quad (69)\]

The spiro stannocanes 404 and 405 were also prepared by the reaction of SnCl\textsubscript{4} with 2 equivalents of the dithiolates (NaSCH\textsubscript{2}CH\textsubscript{2})\textsubscript{2}D (D = NMe, O, S)\textsuperscript{825}. Similar to spirocyclic ‘double germocanes’ 182 and 183, the distortion of the SnS\textsubscript{4} tetrahedral coordination is a result of weak transannular D···Sn (D = O, S) interactions. Thus, the coordination geometry at tin can be described as a bicapped tetrahedron\textsuperscript{825}. The lengths of transannular bonds are 2.84, 2.78 Å (O···Sn in 404) and 3.24, 3.074 Å (S···Sn in 405), respectively.

According to \textsuperscript{119}Sn NMR data, the tin atom in solutions of 403 is hexacoordinated while the coordination in the O and S analogues is closer to tetrahedral (\(\delta(\textsuperscript{119}\text{Sn}) = -198.9, -21.7, -17.1\), respectively, in 301K in Py)\textsuperscript{824}.

A general approach to 4,6-dicarbastannocanes 394–396 is based on the reaction of difunctional Grignard reagents with SnCl\textsubscript{4}, SnBr\textsubscript{4} or PhSnCl\textsubscript{3} in THF/toluene under sufficient dilution (equations 70a and 70b).

\[
\text{SnX}_4 + \text{D}(\text{CH}_2\text{CH}_2\text{CH}_2\text{MgX})_2 \rightarrow \text{X}_2\text{Sn}(\text{CH}_2\text{CH}_2\text{CH}_2)_2\text{D}
\]

\[\text{X} = \text{Cl, Br}; (394\text{a}) \text{ D} = \text{NR}, (395\text{a}) \text{ D} = \text{O}, (396\text{a}) \text{ D} = \text{S} \quad (70\text{a})\]

\[
\text{PhSnCl}_3 + \text{D}(\text{CH}_2\text{CH}_2\text{CH}_2\text{MgCl})_2 \rightarrow \text{ClPhSn}(\text{CH}_2\text{CH}_2\text{CH}_2)_2\text{D}
\]

\[\text{D} = \text{NR}, (305\text{b}) \text{ D} = \text{O}, (396\text{b}) \text{ D} = \text{S} \quad (70\text{b})\]

The yield decreases drastically along the series NMe > O > S and in the case of RN donors also upon substitution of R = Me by other alkyl groups.

The symmetrically substituted tetraorganotin compounds 406a and 407a (R' = Me, \(t\)-Bu, Ph) were obtained in nearly quantitative yields from the reaction of their dichloro precursors with organolithium reagents (equation 71).

\[
\text{Cl}_2\text{Sn}(\text{CH}_2\text{CH}_2\text{CH}_2)_2\text{D} + 2\text{R'}\text{Li} \rightarrow \text{R'}_2\text{Sn}(\text{CH}_2\text{CH}_2\text{CH}_2)_2\text{D}
\]

\[\text{(406a)} \text{ D} = \text{NR}, (407\text{a}) \text{ D} = \text{O} \quad (71)\]
Analogous reaction of the dichlorides Cl₂Sn[(CH₂)₃]₂D 394a and 395a with Ph₃SiONa leads to the corresponding disilox derivatives (Ph₃SiO)₂Sn[(CH₂)₃]₂D 406b and 407b (R = Me, CH₂Ph, i-Bu; R’ = OSiPh₃)⁵³⁰.

One methyl group in the tetraorganotin compounds 406a and 407a (R’ = Me) may be cleaved easily by R’’₃SnX (equation 72)⁸²¹,⁸²⁸.

\[
\text{Me}_2\text{Sn(CH}_2\text{CH}_2\text{CH}_2\text{)}_2\text{D} + R’’₃\text{SnX} \rightarrow X\text{MeSn(CH}_2\text{CH}_2\text{CH}_2\text{)}_2\text{D} + R’’₃\text{SnMe}
\]

(72)

R’’₃SnX = Pr₃SnF, Me₃SnCl

(406c) X = F, Cl; D = NMe₂

(407c) X = Cl; D = O

The monofluoride 406c (X = F) that was isolated as a hydrate from the reaction in equation 72 is apparently the first and only example of a stannocane with fluoride substituent at the Sn atom⁸²⁸.

One methyl group in the dimethyl derivatives 406a (R = R’ = Me) may be also cleaved by the reaction with t-BuPO(OH)₂²⁴⁰. According to the X-ray data, the t-butylyphosphonic acid ligand in the resulting nonsymmetrically substituted stannocane [t-BuP(O)(OH)O]MeSn(CH₂CH₂CH₂)₂NMe 408 coordinates with the tin center only via the oxygen atom.

New types of carbostannocanes were prepared from the dichloride 394a and the monochloride 406c, X = Cl. Spirocyclic compound 409 was obtained in high yield by the reaction of 394a with H₂S in the presence of Et₃N⁸²⁷. Furthermore, the reaction of 394a with sodium naphthalenide in THF at −70°C yields the thermally stable distannane 410a⁸²⁹. Its Me analogue 410b was prepared by a similar method from 406c and Na/NH₃⁸²⁹.

Hexacoordinated stannocanes MeOOCCH₂CH₂(DMTC)Sn(ZCH₂CH₂)₂D 411a (Z = O, D = NMe) and 411b (Z = S, D = O) were prepared by the reaction of MeOOCCH₂CH₂(DMTC)SnCl₂ with (NaZCH₂CH₂)₂D⁷⁵¹.

The Pb analogues of germocanes and stannocanes are almost unknown. The rare examples known include 4,6-dithiaplumbocanes Ph₂Pb(SCH₂CH₂)₂D 412 (D = O) and 413 (D = S), which were prepared from lead diacetate and the corresponding disodium.
dithiolate\textsuperscript{200,830}. According to \textsuperscript{207}Pb NMR data, the 1,5-transannular \( S \rightarrow \text{Pb} \) interaction in \textbf{413} is weaker than the \( O \rightarrow \text{Pb} \) coordination in \textbf{412}. X-ray studies of \textbf{412} show that in the crystal there are two modifications (orthorhombic and triclinic) of the compound. Both contain four crystallographically independent 8-membered cycles that have three chair–chair and one boat–chair conformations. The tetrahedral \( \text{C}_2\text{PbS}_2 \) configuration is expanded by one 1,5-transannular \( O \rightarrow \text{Pb} \) interaction (2.85 to 3.08 \( \text{Å} \), monocapped). In one of the triclinic modifications an intermolecular \( S \cdots \text{Pb} \) interaction takes place (4.11 and 3.75 \( \text{Å} \), bicapped)\textsuperscript{830}.

Evidence for the 1,5-transannular \( D \rightarrow \text{Sn} \) interaction in stannocanes was obtained from X-ray data and Mössbauer spectroscopy in the solid state and in solution also from NMR spectroscopy, especially from the coupling constants \( 1J(\text{\textsuperscript{119}Sn}−D) \), \( D = \text{\textsuperscript{15}N} \), \( \text{\textsuperscript{31}P} \) and \( 2J(\text{\textsuperscript{119}Sn}−D−\text{C}−\text{H}) \). The high-field shift of these compounds in the \textsuperscript{119}Sn NMR spectra compared with compounds of coordination number four with similar substituents at tin as well as the change of the \( 1J(\text{\textsuperscript{119}Sn}−\text{\textsuperscript{13}C}) \) and \( 2J(\text{\textsuperscript{119}Sn}−\text{C}−\text{H}) \) coupling constants are in agreement with pentacoordination\textsuperscript{820,827,831}. It is noteworthy that the relationship between the increasing coupling constants and the increase in the coordination number of the tin atom is valid only for the equatorially bonded organic groups in a TBP arrangement. As a result of the \( D \rightarrow \text{Sn} \) donor–acceptor interaction, the configuration of the tin atom is more or less distorted TBP with two basic configurations, \textbf{414A} and \textbf{414B}, depending on the nature of the substituents.

![Diagram](image)

(\textbf{414A})

(\textbf{414B})

There is NMR evidence for each of the structures\textsuperscript{831–834}. Moreover, in some cases there is indication of the presence of an equilibrium mixture of the two forms in solution\textsuperscript{831}. At lower temperatures a fast intramolecular exchange (Berry-type pseudorotation) was assumed. At a higher temperature, a dissociation–inversion process shows the magnetic equivalence of the \( X \) and \( Y \) groups when \( X = Y \).

In particular, NMR data support the structure \textbf{414A} for \( \text{R}_2\text{Sn(SCH}_2\text{CH}_2)_2\text{NMe} \) \textsuperscript{(391, \( R = \text{Me, \textit{t}-Bu} \))\textsuperscript{833} and the structure \textbf{414B} for \( \text{(\textit{t}-Bu)}_2\text{Sn(OCH}_2\text{CH}_2)_2\text{NMe} \) (the \textbf{388} type)\textsuperscript{832,834}.

According to X-ray data, the molecules of all known 4,6-dicarba- and 4,6-dithiastannocanes (Tables 58 and 59) have configuration \textbf{414A}, where the donor atom \( D \) (\( \text{NR, O, S} \)) and \( X_{ax} \) (\( X = \text{Hal, OSiPh}_3\), \( \text{OPO(OH)Bu-t} \)) are axial ligands while two \textit{S} or \textit{C} atoms (\( Z \)) and \( Y_{eq} \) (\( X = \text{Hal, OSiPh}_3\), \( \text{Me, Ph} \)) occupy the equatorial positions. In the nonsymmetrically substituted alkyl halide or phenyl halide compounds, the halogen substituent is always axial. Furthermore, in the case of the methyl phenyl 4,6-dithiastannocane \textbf{392} (\( X = \text{Ph, Y} = \text{Me} \)) the more electronegative phenyl substituent also occupies the axial position. In the nonsymmetrical compounds, the axial bonds are always longer than the equatorial bonds.

The coordination environment of the tin atom in the three compounds \( \text{Cl}_2\text{Sn(CH}_2\text{CH}_2\text{CH}_2)_2D \) (\( D = \text{NMe, O, S} \)) is more or less distorted TBP due to the
presence of a D → Sn interaction. The donor D and one of the Cl atoms are axial while the second chlorine occupies an equatorial position. A peculiar feature of the structure of bis-stannocane 399 is nonsymmetrical configurations of the two stannocane fragments in the solid state. While both tin atoms have TBP geometries, one Ph group occupies an axial position and another one is equatorial. At the same time the N → Sn distances are almost the same (ca 2.65 Å). The spirostannocane 409 contains a nearly planar Sn₂S₂ four-membered ring with different Sn–S distances for the apical (2.53 Å) and the equatorial (2.40 Å) atoms.

While no short intermolecular contacts were detected in compounds [X₂Sn(SCH₂CH₂)₂O (X = Cl, Br, I)] and [X₂Sn(SCH₂CH₂)₂S (X = Cl, Br, I)], such expansion of the coordination sphere was assumed for compounds [X₂Sn(SCH₂CH₂)₂NMe (X = Cl, Br, I)] on account of their low stability and high melting points. This assumption is in accordance with the facile formation of an adduct of Cl₂Sn(SCH₂CH₂)₂NMe with HMPA. The ¹¹⁹Sn NMR data indicate a hexacoordinated tin atom in the adduct.

The ‘path’ from a tetrahedron to a trigonal bipyramid is controlled by four electronic factors (donor strength of D, electronegativity of the substituent Xₘ, lone pair interaction of Xₘ, type of equatorial ligands) and one steric factor (geometrical flexibility of X). These influences are discussed with respect to the structural and spectroscopic data (i.e. geometrical goodness of the trigonal bipyramid, Pauling-type bond orders BO(D → Sn) and BO(Sn–Xₘ), force constants f(Sn–Xₘ) and ¹¹⁹Sn-NMR chemical shifts). The D → Sn–Hal interaction in the compounds under discussion is given a qualitative MO description in terms of frontier orbitals (a related qualitative description of stannane anions is given elsewhere).

As for the influence of Xₘ, the electronegativity and lone pair interaction effects are counteractive and cancel each other, for the two heavier halides.

Finally, the donor strength of D in compounds [X₂Sn(SCH₂CH₂)₂D (D = NMe, O, S; X = Cl, Br, I)] decreases in the orders: NMe > S > O in the solid state and NMe > O > S in solution.

TABLE 58. Selected structural parameters for 4,6-dicarbostannocanes XYSn(CH₂CH₂CH₂)₂D (394–396).
In most stannocanes the pentacoordination state of the tin atom is retained in solution. This was confirmed by the high-field shifts of the signals of these compounds in the $^{119}$Sn NMR spectra compared to model tetracoordinated compounds. This is confirmed by the increase in the coupling constants $J$ for the equatorially bonded carbon atoms in a TBP arrangement as in 4,6-dicarbastannocanes and also by the coupling constants $J$ for the TBP configuration is retained in solution, but also allow one to estimate the strength of the donor–acceptor interaction. This is especially important for compounds where X-ray data are not available.

The $^{119}$Sn spectra of Cl(n-Bu)Sn(SCH$_2$CH$_2$)$_2$O and Cl(n-Bu)Sn(SCH$_2$CH$_2$)$_2$S show unique $\delta$ values at $-10.93$ and $-8.85$ ppm, respectively. Such chemical shifts

$a$ $^1J(^{119}$Sn$-^{13}$C$_{eq}) = 131$ Hz.

$b$ $^1J(^{119}$Sn$-^{13}$C$_{eq}) = 131$ Hz.

are outside the proposed range$^{542}$ for pentacoordinated tin (between $ca. -90$ and $-330$ ppm), although similar signals were detected for several other pentacoordinated compounds, such as O(CH$_2$CH$_2$)$_2$Sn(CH$_2$CH$_2$COOMe)Cl ($-18.4$ ppm)$^{738}$ and Br$_2$Sn(SCH$_2$CH$_2$)$_2$O ($-40.9$ ppm)$^{819}$. 

\[ \text{Reference} \]
Solid-state investigations show that stannocanes $\text{RR}^{'\prime}\text{Sn}((\text{SCH}_2\text{CH}_2)_2\text{D})$ ($\text{D} = \text{NMe}, \text{O}, \text{S}$) have either chair–chair (CC) and boat–chair (BC) conformations of the eight-membered cycles or some intermediate structures between these two conformations. CC and BC conformations were assumed for compounds $[\text{X}_2\text{Sn}((\text{SCH}_2\text{CH}_2)_2\text{O})]$ ($\text{X} = \text{Cl, Br, I}$) and $[\text{X}_2\text{Sn}((\text{SCH}_2\text{CH}_2)_2\text{S})]$ ($\text{X} = \text{Cl, Br, I}$), respectively. The molecules of stannocanes $\text{Cl}_2\text{Sn}((\text{CH}_2\text{CH}_2\text{CH}_2)_2\text{D})$ ($\text{D} = \text{NMe}, \text{O}, \text{S}$) have CC, BC or boat–boat (BC) conformations, respectively.

Substitution of one chlorine atom in $\text{Cl}_2\text{Sn}((\text{CH}_2\text{CH}_2\text{CH}_2)_2\text{NMe})$ by a second tin fragment in $[\text{ClSn}((\text{CH}_2\text{CH}_2\text{CH}_2)_2\text{NMe})_2]$ shifts the conformation of the eight-membered cycle toward the BC state while the Sn–N distances in both compounds are nearly the same.

If the secondary bonding is strong enough, the conformation becomes boat–boat, but when the bond strength decreases, the preferred conformation is boat–chair and then a chair–chair arrangement.

A quantitative measure for the position of a given structure on the pathway between tetrahedron and TBP is the displacement ($\Delta_{\text{Sn}}$) of the central atom from equatorial plane and the difference between the sums of the equatorial and axial angles, $\Delta \Sigma (\theta)$. Selected structural parameters of known stannocanes are summarized in Tables 58 and 59.

The transition from the dimethylstannocanes $\text{Me}_2\text{Sn}((\text{CH}_2\text{CH}_2\text{CH}_2)_2\text{D})$ ($\text{D} = \text{NMe, O}$) to the monochlorides $\text{ClMeSn}((\text{CH}_2\text{CH}_2\text{CH}_2)_2\text{D})$ ($\text{D} = \text{NMe, O}$) leads to low-field shifts of the $^{119}\text{Sn}$ signals in the NMR spectra while the signals of the dichlorides $\text{Cl}_2\text{Sn}((\text{CH}_2\text{CH}_2\text{CH}_2)_2\text{D})$ ($\text{D} = \text{NMe, O}$) are shifted upfield as a result of the so-called ‘U-shape’ dependence of $\delta(^{119}\text{Sn})$ on the number of electronegative substituents at the tin atom.

The dynamic processes observed by NMR studies are interpreted in terms of a dissociation–inversion (DI) mechanism or an ‘in-out’ equilibrium. The dynamic behavior of the 4,6-dicarbastannocanes is interpreted in terms of a combined DI and ring-inversion mechanism.

2. Bicyclic analogues of stannocanes

Diorganotin complexes containing a tridentate ligand are among hypervalent organotin compounds which are of interest owing to their antitumour activity and include $\text{N}_x\text{N}_y\text{O}_z$, $\text{N}_x\text{O}_y\text{O}_z$, $\text{N}_x\text{O}_y\text{S}_z$- and $\text{O}_x\text{C}_y\text{O}_z$-chelates. Early examples of dipeptide derivatives with the common structure established by X-ray studies are: $(\text{t-Bu})_2\text{Sn}(\text{Gly-GlyO})$, $\text{Ph}_2\text{Sn}(\text{Gly-GlyO})$, $(\text{c-Hex})_2\text{Sn}(\text{Gly-AlaO})$, $\text{Et}_2\text{Sn}(\text{Gly-ValO})$, $\text{Me}_2\text{Sn}(\text{Gly-MetO})$ and $\text{Et}_2\text{Sn}(\text{Gly-TyrO})$. The polyhedron around Sn in all complexes bearing a dianionic N,N,O-chelate ligand corresponds to that found in diorganogermainium derivatives of dipeptides (Section VI.B). It is a distorted TBP with the peptide nitrogen and two carbon atoms in equatorial positions and the oxygen of the unidentate carboxylate group and the amino nitrogen in the apical positions. The tridentate dipeptide ligands are usually nearly planar. The $\text{N}_{ax}$–Sn bond lengths at 2.25–2.30Å are significantly longer than the $\text{N}_{eq}$–Sn distances (around 2.10Å). The
latter are very short and even shorter than the sum of the N and O covalent radii (2.154 Å, see Table 1), indicating a strong bond. The analogous Sn—N(peptide) bond of Me₂(SnGlyGlyO) resists fast hydrolysis in solution, in contrast to the two apical bonds of Sn to the amino N and carboxylate O⁸⁵¹.

One of the two tin atoms in [Et₂Sn(Gly-HisO)]₂·MeOH has a TBP environment, as above, while the second is hexacoordinate⁸⁵². Recently, the molecular dynamics of tryptophan-containing dipeptide complexes, i.e. Me₂Sn(Trp-AlaO), Ph₂Sn(Trp-AlaO) and Me₂Sn(Trp-TyrO), were investigated by a variable-temperature ¹¹⁹Sn Mössbauer spectroscopy⁸⁵³. The complexes behaved as Debye solids and, in particular, the calculated mean-square displacements of the tin atom confirm the occurrence of monomeric structures. An X-ray diffraction of Me₂Sn(Trp-AlaO)·MeOH reveals a distorted TBP arrangement at the tin center, with the two methyl carbons (C—Sn—C123°) and the deprotonated peptide nitrogen (Neq—Sn 2.064 Å) in equatorial positions while the terminal amino nitrogen (N→Sn 2.272 Å) and the terminal carboxylate oxygen are in apical positions (O—Sn—Nax151.5°).

The pentacoordinate organotin compounds ⁴¹⁶a–c also contain a tridentate dianionic N,N,O-chelate ligand⁸⁵⁴,⁸⁵⁵. The structure of ⁴¹⁶c⁸⁵⁴ was determined by X-ray diffraction which conformed the rigid polycyclic structure proposed on the basis of ¹H, ¹¹B, ¹³C, ¹⁵N and ¹¹⁹Sn NMR data in solution (δ¹¹⁹Sn −150.4 ppm)⁸⁵⁵. In contrast, the dimethyltin compound ⁴¹⁶a displays a fluxional structure in solution.

Several series of bicycloazastannoxides bearing dianionic N,O,O-chelate ligands were described. Diorganotin 2,6-pyridinedicarboxylates 2,6-C₅H₃N(COO)₂SnRR¹ ⁴¹⁷ (R, R¹ = Me, Et, Pr, i-Pr, Bu, Ph) were investigated for antitumour activity⁸⁵⁶,⁸⁵⁷. Among them, organotin derivatives of 1,2- and 1,7-dicarba-closo-dodecaboranes, ⁴¹⁷a (R = R¹ = o-(C₂B₁₀H₁₁-9)) and ⁴¹⁷b (R = R¹ = m-(C₂B₁₀H₁₁-9)), were recently synthesized by the reaction of the corresponding ortho- and meta-carboranyl tin oxides with 2,6-pyridinedicarboxylic acid and their structures were proved by ¹¹⁹Sn Mössbauer, ¹H, ¹³C and ¹¹⁹Sn NMR spectroscopy⁸⁵⁸.

Other representatives of the N,O,O-chelates are diorganotin-N-arylidene-α-amino acid complexes (⁴¹⁸)⁸⁵⁹,⁸⁶⁰, including ⁴¹⁸a⁸⁵⁹ and ⁴¹⁸b⁸⁶⁰, for which five-coordinate monomeric structures were established by X-ray studies. The tridentate ligands in these compounds are near-planar. The tin centers have a distorted TBP geometry with the two
carbon atoms and the imino nitrogen in the equatorial positions and the two oxygens in the axial positions. The OSnO angles are 155.9°, 157.2° and 159.4°(av) for \(418\text{a}, 418\text{b}\) and \(418\text{c}\), respectively (see below). The two axial Sn—O bonds (2.15 and 2.08 Å in \(418\text{a}\), 2.12 and 2.09 Å in \(418\text{b}\) and 2.129 (av) and 2.061 (av) Å in \(418\text{c}\) and the corresponding equatorial N → Sn bond of 2.13, 2.14 and 2.189 (av) Å are among the shortest reported for related complexes. The shorter O—Sn bond length involves the phenolic oxygen.

![Diagram of \(418\text{a}\) and \(418\text{c}\)](image)

\(418\text{a}\) R = Bu, R\(^1\) = i-Pr, R\(^2\) = R\(^3\) = R\(^4\) = H
\(418\text{b}\) R = Ph, R\(^1\) = R\(^2\) = H, R\(^3\)R\(^4\) = o-C\(_6\)H\(_4\)
\(418\text{c}\) R = Ph, R\(^1\) = H, R\(^2\) = Me, R\(^3\) = R\(^4\) = H

A similar geometry is found for bicycloazastannoxide \(419\text{a}\) (OSnO 159.5°, O—Sn 2.103 and 2.085 Å, N → Sn 2.241 Å)\(^861\), the salicylhydrazone derivatives \(420\text{a}\) and \(420\text{b}\) (OSnO 153.5°, O—Sn 2.160 and 2.094 Å, N → Sn 2.174 Å in \(420\text{a}\)\(^862\), and OSnO 156.2° and N → Sn 2.152 Å in \(420\text{b}\)\(^863\) and for both tin atoms in the ditin species \(421\text{a}\) (OSnO 151.4°, O—Sn 2.059, O → Sn 2.210, and N—Sn 2.133 Å)\(^864\).

The reactions of mono-sodium or -potassium salts of \(N-(2\text{-hydroxyacetophenone})\)glycine with dichlorides \(R_2\text{SnCl}_2\) (R = t-Bu, Vin, Ph) were recently investigated yielding glycinate, \(418\text{c}\), only for R = Ph\(^865\). In the other cases, the adducts with (t-Bu)\(_2\)SnCl\(_2\), \(422\text{a}\), and with a water molecule, Vin\(_2\)Sn(2-OC\(_6\)H\(_4\)C(Me)==NCH\(_2\)COO)-H\(_2\)O \(423\), respectively, were isolated from the reaction mixtures. In turn, reaction of \(418\text{c}\) with Ph\(_3\)SnCl yielded the 1 : 1 adduct \(422\text{b}\) in which the two tin atoms, like in \(422\text{a}\), are joined via the carbonyl atom of the ligand to form a rare mixed diorganotin/triorganotin species.

X-ray structural determinations of \(418\text{c}\) reveal that the polyhedron around Sn in \(418\text{c}\) is a distorted TBP with nitrogen and two carbon atoms in equatorial positions and two
Oxygens of the phenolic and unidentate carboxylate groups in the apical positions. Similar features are found in structures 422a and 422b, except for the presence of bidentate bridging carboxylate residues. A comparison of chemically equivalent geometric parameters for 418c with those about the Sn1 atom in 422b shows remarkable consistency; the Sn1 atom lies 0.032 Å in 418c and 0.038 Å in 422b, respectively, out of the trigonal plane in the direction of the phenolic oxygen. Unlike in complexes 418c, 422a and 422b, the tin atom in 423 is six-coordinate and distorted octahedral due to the coordination of a water molecule. NMR data indicate that the 1 : 1 adducts 422a, 422b and 423 dissociate in noncoordinating solvents with formation of five-coordinate species.

Chelates 419b and 424 are examples of diorganotin complexes with a tridentate dianionic ligand bonding through three different donors — N, O and S. According to the X-ray data, the tin atom in these compounds is five-coordinate and has a distorted TBP arrangement with equatorial nitrogen and two carbons. A similar geometry was found for chelate, 425, which is a rare example of a diorganotin complex containing a tridentate trianionic ligand. Corresponding geometric parameters for 419b and its oxo analogue 419a are very similar (OSnS 157.4° against 159.5° for OSnO in 419a; 2.093 and 2.217 Å for O—Sn and N → Sn, respectively, against 2.085 and 2.241 Å in 419a). In the case of 425, the OSnO angle is 151.6° and both O—Sn and N—Sn distances are 2.111, 2.115 and 2.146 Å, i.e. close to the corresponding ordinary bonds in such complexes.
A special feature of chelates 421a\textsuperscript{864} and 424\textsuperscript{867} is a coordinative O → Sn bond, but not an N → Sn bond as in other chelates, with tridentate ligands discussed in this section. In consequence, the N–Sn distances of 2.133 and 2.147 Å in 421a and 424, respectively, are shorter than those, e.g., in 419a and 419b (see above) and the O → Sn bond lengths of 2.210 and 2.164 Å are correspondingly longer. The S–Sn distances in both thio complexes, 419b and 424, are practically equal (2.496 and 2.502 Å).

The five-coordinate complexes of type 421 possess a rigid structure, which is retained in solution as indicated by comparing the $^{119}$Sn NMR in solution and in the solid state\textsuperscript{864}. For 421a–c, isotope-induced chemical shifts $^1\Delta^{12/13}$C($^{119}$Sn) were determined for the first time for five-coordinate tin nuclei at natural abundance of $^{13}$C. A positive sign of $^1\Delta^{12/13}$C($^{119}$Sn) was found, in contrast with most tetracoordinate organotin compounds.

The synthesis of the first monoanionic O,C,O-pincer ligand 4-\textit{t}-Bu-2,6-[PO(OEt)$_2$]$_2$C$_6$H$_2$ and its application for the preparation of penta- and hexacoordinate species were reported most recently (Scheme 19)\textsuperscript{147,762,769}. Attempts to synthesize organotin cations starting from intramolecularly coordinated organotin compounds 426a and 426b resulted in an intramolecular donor-assisted cyclization reaction with elimination of EtCl (EtX, PhH or PhX) leading to neutral pentacoordinate 2,3,1-benzoxaphosphastannole derivatives 427a and 427b or hexacoordinate dihalides 428a and 428b. A similar dihalide was isolated by treatment of 427a with an excess of Me$_3$SiBr. Pentacoordinate cationic tin species of the type 429, which may be described by two resonance structures, are suggested as intermediates in these cyclizations.

X-ray crystallography of stannole 426a revealed a slightly distorted TBP center, with the two oxygens occupying axial positions (OSnO 160.2°, O–Sn 2.125, O → Sn 2.396 Å) and the three carbon atoms occupying equatorial positions\textsuperscript{769}. The configuration at tin can be classified as being located on the T → TBP pathway\textsuperscript{818,819}. The estimation of the position along this path by using the difference between the sums of the equatorial and axial angles (0° for the ideal T, 90° for ideal TBP) gives a value of 77.7° for 426a. The tin atom deviates from the equatorial plane by 0.136 Å away from the dative O → Sn bond.

The action of an excess Me$_3$SiBr on 426a led to its complete transesterification product, 4-\textit{t}-Bu-2,6-[PO(OSiMe$_3$)$_2$]$_2$C$_6$H$_2$SnPh$_3$. The subsequent treatment of the latter with water afforded 2,3,1-benzoxaphosphostannole 4-\textit{t}-Bu-2,6-[PO(OH)$_2$]$_2$C$_6$H$_2$SnPh$_2$ and benzene. As a result of the high donor capacity of the intramolecularly coordinated phosphonyl groups, the similar reaction of stannole 427a with Me$_3$SiBr proceeds with Sn–C rather than P–O(Sn) bond cleavage, yielding the hexacoordinate dibromide 4-\textit{t}-Bu-2-[PO(OEt)$_2$]-6-[PO(OEt)(OSiMe$_3$)]C$_6$H$_2$SnPhBr$_2$ which is related to dihalides 428a and 428b.
Finally, the hexacoordinate trichloride 430 also undergoes intramolecular cyclization by heating to provide the dimeric dichloro-substituted 2,3,1-benzostannole 431 as a mixture of the two diastereomers (equation 73). An X-ray crystal structure analysis of the major diastereomer of 431 shows that the tin centers adopt a distorted octahedral coordination geometry owing to both intermolecular and intramolecular O—Sn interactions with the phosphonyl group acting as a bidentate bridging ligand.

SCHEME 19. Intramolecular cyclization of organotin compounds bearing O,C,O-coordinating ligand
16. Hypervalent compounds of organic germanium, tin and lead derivatives

C. Tricyclic Complexes

1. Stannatranes and their analogues

a. Synthesis and reactivity. Several main types of stannatranes, 432–436,554,820 and their tricyclic analogues, such as tribenzostannatranes 437, 438,554,555,820, stannatranones 439,555,820,869 and azastannatranone 440,869, carbastannatranes 441 and 442,827,828, thia- stannatranes 443 and azastannatranes 444–447,870,871, have been described.

Generation of atrane framework in stannatranes and their analogues may be generally performed by the same methods applied to the corresponding derivatives of germanium (Section VI.C.1.a). For example, re-alkoxylation (similar to equation 48) was used for the preparation of 1-organostannatranes 432, 1-alkoxystannatranes 433 and 1-organoazastannatranones 439,554,603. Reactions of polyorganostannosesquioxides \( (RSnO_1)_n \) or polyorganostannonic acids \( [RSn(O)OH]_n \) with TEAA in aromatic solvents with and without KOH proceed similarly to equation 49 and lead to analogous products,554,820. 1-Organothiastannatranes 443 were prepared from polyorganostannonic acids and tris(2-mercaptoethyl)amine in the presence of KOH,554,820. Preparation of atranes 432 or 443 from polydiorganostannoxides includes elimination of one organic radical from the tin atom (equation 74),554,820.

\[
1/n(R_2SnO)_n + (HYCH_2CH_2)_3N \xrightarrow{\text{xylene, KOH}} RSn(YCH_2CH_2)_3N \quad (432) Y = O \\
(433) Y = S 
\]

Reaction of mixed polydiorganostannoxides (RPhSnO)_n with aminotriacetic acid proceeds with elimination of the phenyl group and gives stannatranones 439,869.

Use of other types of organotin compounds for the preparation of stannatranes is less common. Alcoholysis of aminostannane \( Sn(NMe_2)\_4 \) with TEAA and methanol was used for the synthesis of 1-methoxystannatranate 433 (R = Me),554. Reaction of tetraacyloxystannanes with \( (Et_3SnOCH_2CH_2)_3N \) leads to acyloxystannatranes 434 (R = Me),554 while 1-alkylstannatranes 432 were prepared from \( RSnCl_3 \), TEAA and MeONa,554.

Reaction between \( Me_2N(CH_2)_3Sn(OPh)Ph_2 \) (239e) and TEAA proceeds smoothly due to the high reactivity of hypervalently activated organotin compounds and gives stannatran 432 (R = (CH_2)_3NMe_2),644. Its \( ^{119}\text{Sn} \) NMR appears between those of stannatranes with penta- and hexacoordinated tin atoms. This fact was interpreted as a result of a fast equilibrium on the NMR time scale.
Similar reactions of $^{239}$e or Me$_2$N(CH$_2$)$_3$SnPh$_3$ (228) and nitrilotriacetic acid led to the formation of stannatranone 439 ($R = (\text{CH}_2)_3\text{NMe}_2$) and, unexpectedly, to the N-oxide derivative 439 ($R = (\text{CH}_2)_3\text{N(O)Me}_2$). According to X-ray data, the latter contains a pentacoordinate tin with intramolecular Sn–N and Sn–O distances of 2.231 and 2.101 Å, respectively$^{644}$.

The C–Ph bond in compounds 432 ($R = \text{Ph}$) or 438 may be cleaved easily by I$_2$ or HgI$_2$, leading to formation of PhI or PhHgI and the corresponding iodo derivatives or cation–anion complexes with tetrahedral tin in the cation and a HgI$_3^{–}$ anion$^{555}$.

Initial approaches to carbastannatranes 441 and 442 were based on the reaction of SnCl$_4$ with the trifunctional Grignard reagent N(CH$_2$CH$_2$CH$_2$MgCl)$_3$ or of Me$_2$SnCl$_2$ with tris(stannyl)amine N(CH$_2$CH$_2$CH$_2$SnMe$_3$)$_3$. Both methods led to chloride 442b (442,

---

(432) $X = R$
(433) $X = \text{OR}$
(434) $X = \text{OCOR}$
(435) $X = \text{Hal}$

(437) $X = \text{Alk}$
(438) $X = \text{Ph}$

(439) $X = \text{R, } Y = O$
(440) $X = \text{R, } Y = \text{NMe}$

(441) $X = \text{R}$
(442) $X = \text{Hal}$

(443) $X = \text{R, } Y = S$
(444) $X = \text{R, } Y = \text{NH}$
(445) $X = \text{R, } Y = \text{NMe}$
(446) $X = \text{NMe}_2, Y = \text{NMe}$
(447) $X = \text{Hal, } Y = \text{NMe}$
X = Cl$^{827}$. Introduction of SnCl$_4$ into the last reaction gave the product under milder conditions in higher yields$^{872}$. Reaction of 442b with methylolithium gave 441, R = Me (441a)$^{826, 827}$. Carbastannatrane 441a was recently exchanged with Pr$_3$SnF and gave 1-fluorocarbastannatrane 442a; the latter was also prepared by exchange reaction of halides 442b–d ((b) X = Cl, (c) X = Br, (d) X = I) with Bu$_4$NF·H$_2$O$^{828}$. In all the reactions the fluoride 442a was isolated and characterized as monohydrate 442a·H$_2$O.

Due to the relative lability of the apical Sn–R bond in carbastannatranes 441, these compounds are interesting synths for further chemical transformations$^{636, 873}$. For example, under ultrasonic induction even methanol is capable of splitting the Me–Sn bond in carbastannatrane 441a$^{819}$.

Transamination reaction similar to equation 60 is also a general approach to azastannatranes. In the case of tin the reaction proceeds more readily (at room temperature and without catalyst) than for germanium derivatives and the yields of the desired products 444 and 445 (R = Me, n-Bu, t-Bu, Ph) and 446 are generally higher$^{820, 870, 874}$. The axial NMe$_2$ group in 446 is labile to substitution, affording either 1-haloazastannatranes 447 (Hal = F, Cl, Br, I) in reactions with corresponding ammonium salts or 1-(phenylalkynyl)-N,N',N''-trimethylazastannatrane and bis(N,N',N''-trimethylazastannatranyl)acetylene in reactions with phenylacetylene or acetylene, respectively$^{875}$.

Compound 445 (R = n-Bu) demonstrates the ability of azastannatranes to participate in transmetallation reactions with metal alkoxides N≡Mo(OBu-t)$_3$, OV(OPr-i)$_3$ or N-substituted tris(siloloy)vanadium(V) imides to prepare N≡Mo(NMeCH$_2$CH$_2$)$_3$N$^{874}$, O≡V(NMeCH$_2$CH$_2$)$_3$N$^{874}$ and RN≡V(NMeCH$_2$CH$_2$)$_3$N (R = SiMe$_3$, CMe$_3$)$^{871}$, respectively, in high yields.

Reaction of carbastannatrane 442b (Hal = Cl) with AgBF$_4$ yields the tetrafluoroborate salt [N(CH$_2$CH$_2$CH$_2$)$_3$Sn]$^+$BF$_4$$. Its ionic structure in solution was confirmed by $^{119}$Sn NMR chemical shift (103 ppm), which indicate a tetracoordinate tin atom$^{827, 876}$. However, reactions of azastannatranes 445 (R = Me, n-Bu, Ph) with BF$_3$·Et$_2$O lead to six-coordinated compounds 448 (equation 75)$^{877}$.

The tricyclic atrane framework is preserved under hydrolysis conditions and the hydrolysis product 449 is formally an adduct of 445, R = Me with HF and HBF$_4$ (equation 75). According to X-ray data, the ionic 449 contains a six-coordinate tin atom, with the cation stabilized by three coordinating amino groups$^{877}$.

The first stannatrane containing a tin–metal bond, the osmium derivative 450, was synthesized from TEAA and a triiodostannylosmium complex (Scheme 20)$^{878}$.

b. Structure and physical properties. In contrast to germatranes, the stannatranes without bulky substituents at the tin atom are capable of participating in additional intermolecular interactions. Most stannatranes form intermolecular associates in their crystals. These compounds are moderately stable in water and soluble in polar solvents. The solubility decreases at lower temperatures, possibly as a result of oligomerization. Molecules of stannatranes are noticeably associated in concentrated solutions. For example, 1-methylstannatrane (432a) forms trimers in nonpolar solvents whereas 1-t-butylstannatrane (432b) exists only as monomer in all solvents studied$^{554, 820, 879}$. In contrast to regular stannatranes, thiastannatranes 443 (R = Me, t-Bu) and azastannatranes 444–447 are always monomeric in solution$^{535, 820}$.

The structures of stannatranes in solution were deduced from the decreased $^2J(^{119}$Sn–C−$^1$H) coupling constants in comparison with similar tetracoordinated compounds (e.g. MeSn(CNMeCH$_2$CH$_2$)$_3$N (i.e. of type 445) $^2J(^{119}$Sn−C−$^1$H) = 61.0 Hz; MeSn(NEt$_2$)$_3$68.7 Hz; MeSn(SCH$_2$CH$_2$)$_3$N (i.e. of type 446) 60.0 Hz; MeSn(SEt)$_3$ 65.2 Hz)$^{879}$. The temperature dependence of the NMR spectra of 1-organostannatranes
SCHEME 20. Synthesis of stannatrane 450 containing the tin—osmium bond
substituted by sterically bulky substituents on Sn indicate molecular association in organic solvents. The associates are assumed to have a trimeric cyclic structure. The increase in size of the substituent R (e.g. R = t-Bu, o-MeC₆H₄) decreases the stability of the associates.

Stannatranes (Table 62) were studied less by X-ray diffraction than germatranes (see Table 40). Only some stannatranes have ‘regular’ atrane structures with pentacoordinated tin atom. Compound 432b (R = 2-MeOC₆H₄) was the first monomeric stannatrane for which atomic coordinates were reliably determined. The central atom has a distorted TBP environment, opened slightly toward the methoxy group. Comparison of stannatrane 432b and 1-phenylgermatrane 189a (in particular, the ∆M (M = Ge, Sn) values; see Table 40) suggests a weaker coordination in the tin derivative.

A trimeric structure of 1-methylstannatrane (432a) with a roughly pentagonal bipyramidal central and distorted octahedral terminal atoms of tin has been discussed. Strong association between the molecules results from the presence of bridged oxygen atoms and hydrogen bonds with six molecules of water. At −50 °C the NMR spectra display three resonances, two of which are in the area of hexacoordinated tin compounds (−356.4 and −352.3 ppm) while the third signal (−532.9 ppm) indicates the presence of heptacoordinated tin. The 119Sn chemical shift of a ‘regular’ pentacoordinated 1-t-butyliostannatrane 432c is −245.5 ppm. These facts testify that stannatrane 432a retains its trimeric units in solution.

a Deviation of the Sn atom from equatorial plane toward X.
b Trimer.
c Hexagonal.
d Monoclinic.
e Tetrameric.
f Two independent molecules in the unit cell.
X-ray diffraction of the first metal-bound stannatrane 450 shows that the tin atom has a significantly distorted TBP environment with the Os and N atoms in axial positions. The Sn–N bond length is only a little longer than the distance in 1-organostannatranes 432a–c (Table 62). According to the authors, the virtual absence of N–Si interaction in the Si analogue of 450 (N–Si 3.176 Å; typical values for silatranes are in the range of 2.00–2.26 Å) is indicative of the greater ability of tin compared to silicon to form hypervalent compounds.

In the cation of complex 449, the transannular Sn–N bond length (2.29 Å) is shorter than those in 444c and 446 (Table 62). This difference is ascribed to the positive charge in the cation 449. A slight elongation of the Sn–F bond in 449 (by 0.08 Å) in comparison with a ‘standard’ single Sn–F bond (1.96 Å) is also in agreement with this suggestion.

Carbastannatrane 441a is probably the first pentacoordinated tetraorganotin compound whose crystal structure was confirmed by the X-ray method.

1-Fluorocarbastannatrane (442a) is a tetramer held together by intermolecular Sn···F interactions (ca 2.80 Å) and also by F···H and O···H hydrogen bridges. It is the first example of an intermolecular hexacoordinated triorganotin halide. The average lengthening of the Sn–F bonds is about 0.158 Å compared to an Sn–F single bond (1.96 Å) and, according to the authors, this is a result of intramolecular coordination as well as of intermolecular coordination accompanied by hydrogen bridging. In contrast to 442a, 1-halocarbastannatranes 442b–d (Hal = Cl, Br, I) retain a typical atrane structure with pentacoordinate tin atom. The shortest N→Sn distances have close values. It was suggested that the electronegativity and the lone pair interaction of the halogen substituents are counteractive and compensate one another at bromine.

Comparison of 1-chlorocarbastannatrane 442b with its bicyclic ClPhSn(CH2CH2CH2)2NMe and monocyclic ClR2Sn(CH2)3NMe2 (R = Me, Ph) analogues shows that the N→Sn coordination weakens upon transition from tri- to bicyclic and further to monocyclic systems (Scheme 21). In accordance with the theory of hypervalency, this process is accompanied by the gradual shortening of the second axial bond (Cl–Sn).

2. Other tricyclic derivatives

TBP organotin complexes of the type RSn[E(C6H4O-2)3] (E = N, 437, and E = P, 438), where four of the five coordination sites are occupied by the four donor atoms of a tetridentate tripodal trianionic ligand, are well-known. Most recently, their analogous 451a–e were prepared by the reaction of organotrichlorostannanes with the lithium salt of the corresponding ligand, generated in situ from the thiol and BuLi (equation 76). Compound 451e undergoes a metathesis reaction with FeCl3 to give the purple iron complex ClFe[P(3-Me3SiC6H3-2S)3] in one step.

X-ray structure determinations of 451c–e showed a distorted TBP geometry at tin, which is located above the S3 plane. The distortion from the ideal geometry is illustrated by the CSnP angles of 178.5°, 163.3° and 177.1°, as well as by the sum of the SSnS equatorial angles of 354.1°, 352.6° and 350.4°, respectively. The mean length of the equatorial Sn–S bonds is about 2.51 Å, compared to 2.43 Å of a usual Sn–S bond in tetrahedral compounds. The corresponding P→Sn bond lengths in 451c–e of 2.516, 2.513 and 2.613 Å are shorter than that in the related pentacoordinate organotin complexes 268b and 271d (Section VII.A, Tables 45 and 47).

VIII. PENTACOORDINATE CATIONIC COMPOUNDS

Intermolecular and intramolecular donor–acceptor interactions are known as a means for stabilization of trivalent germeyl \(^{496}\), stannyl \(^{8,636,885–888}\) and plumbyl \(^{889}\) cations.

A. Germanium Intramolecular Complexes

Synthesis of cation–anion complexes \([L_2\text{Ge}(H)(B)]^{1+}\text{OTf}^-\) (123c-B, L is the potential bidentate 8-methoxynaphthyl ligand, B = \(\text{C}_6\text{H}_5\text{CH}_2\text{NH}_2, \text{H}_2\text{O, DMSO}\) containing...
a solvated germyl cation was discussed in Section VI.A.1.a. An X-ray diffraction analysis of $123c \cdot H_2O$ reveals the presence of a dimeric form in which $O-H$ hydrogen bonds between the hydrogen of $H_2O$ and the oxygen atom of the triflate anion connect the two monomers (Scheme 22). The Ge atom shows a slightly distorted TBP geometry with only one methoxy group coordinated to the germanium in each monomer (omitting the rather long $O \cdots Ge$ contact, 2.785 Å, of the second methoxy group). The apical positions are occupied by one methoxy group and an $H_2O$ molecule at a $(Me)OGeO(H_2)$ angle of 168.4°, with $O-Ge$ distances of 2.425 and 1.95 Å, respectively. The deviation of the Ge atom from the equatorial plane defined by the hydrogen and two carbon atoms is 0.27 Å in the direction of the water oxygen. Consequently, water is better leaving from Ge in $S_N-Ge$ reactions as compared to the triflate anion in $123c$, with a coordination site being the same for both compounds. This contrasts drastically with the cation–anion H-associate structure of the hydrochloride PhCONHCH$_2$SiMe$_2$OH $\cdot HCl$ where the central atom has a TBP environment with $O$ atoms in axial positions, but the silicon deviates from the equatorial plane ($\Delta Si$) by 0.024 Å in a direction away from the ‘oxonium’ oxygen atom.

The 1H NMR and IR spectra are consistent with a positively charged germanium center in $123c \cdot H_2O$ showing the low-field chemical shift displacement of the $GeH$ resonance (7.76 ppm) and a very high $v(Ge-H)$ value (2165 cm$^{-1}$).
The reactions of dichlorides \((L^n)_2\text{GeCl}_2\), where \(L\) is the bidentate lactamomethyl C,O-chelating ligand, \(n = 5–7\) (the size of the lactam ring, cf. equation 77), with \(\text{Me}_3\text{SiOTf}, \text{Me}_3\text{SiX}\) \((X = \text{Br, I})\) and lithium or silver salts \((\text{LiBr}, \text{LiI}, \text{LiClO}_4, \text{AgF})\) give rise to two types of compounds, depending on the nature of monodentate ligands in the product\(^{494,496}\). If the nucleofugalities of the entering \((\text{F or Br})\) group is close to that of the leaving \((\text{Cl})\) group, both chlorine atoms are replaced by the nucleophile (Section X.B.2). These reactions proceed with retention of the octahedral configuration of the initial dichlorides, where the carbon atoms are in \textit{trans} positions and the coordinating oxygen and halogen atoms are in \textit{cis} positions with respect to each other. If the nucleofugalities of the entering \((\text{OTf, OCIO}_3, \text{BF}_4, \text{I or I}^3)\) and leaving \((\text{Cl})\) group differ significantly, only one chlorine atom is replaced by the nucleophile regardless of the ratio of reactants \((1 : 1\) or \(1 : 2\)) (equation 77), leading to products \(452–458\) with a change in the coordination of the Ge atom to \((5 + 1)\).

\[
\begin{align*}
(L^n)_2\text{GeX}_2 & \quad \text{MY} = \text{Me}_3\text{SiOTf, Me}_3\text{SiI, LiI, LiClO}_4, \text{AgBF}_4 \\
(\text{X} = \text{Cl, Br}) & \quad (L^n)_2\text{Ge}(\text{X})\text{Y} \\
(452a) & n = 1, \text{X} = \text{Cl, Y} = \text{OTf} \\
(452b) & n = 2, \text{X} = \text{Cl, Y} = \text{OTf} \\
(452c) & n = 3, \text{X} = \text{Cl, Y} = \text{OTf} \\
(453) & n = 3, \text{X} = \text{Br, Y} = \text{OTf} \\
(454a) & n = 1, \text{X} = \text{Cl, Y} = \text{OCIO}_3 \\
(454b) & n = 3, \text{X} = \text{Cl, Y} = \text{OCIO}_3 \\
(455) & n = 3, \text{X} = \text{Cl, Y} = \text{I} \\
(456) & n = 3, \text{X} = \text{Cl, Y} = \text{I}^3 \\
(457) & n = 3, \text{X} = \text{Br, Y} = \text{I} \\
(458) & n = 3, \text{X} = \text{F, Y} = \text{BF}_4 \\
\end{align*}
\]

Analogously, bromide-triflate \(453\) and bromide-iodide \(457\) were synthesized by the reaction of dibromide \((L^7)_2\text{GeBr}_2\) with \(\text{Me}_3\text{SiOTf}\) and \(\text{Me}_3\text{SiI}\), respectively\(^{494}\). Unexpectedly, the fluorotetrafluoroborate \([L^7)_2\text{Ge(}\text{F})_2\text{][BF}_4]\) \(458\) was obtained by replacing one chlorine by fluorine and another one by a \text{BF}_4 group, and treating the corresponding dichloride with \text{AgBF}_4\(^{893}\).

According to X-ray structural determinations (Table 63), the coordination environment at the Ge atom in complexes \(452–458\) is intermediate between an Oh and a TBP with the C and O atoms and the monodentate ligands located in \textit{trans} positions relative to each other. Consequently, in triflates \(452a–c, 453\) and perchlorate \(454b\) the Ge atom has octahedral coordination strongly distorted toward a monocapped TBP, while the iodides \(455, 457\) and the triiodide \(456\) are almost ionic with weak Ge···I coordination \((4.18–4.26\ \text{Å})\). The Ge–Cl bond lengths in \(452a–c, 454a, 455\) and \(456\) \((2.13–2.21\ \text{Å})\), as well as the Ge–Br bond lengths in \(453\) and \(457\) \((2.31\ \text{and} 2.37\ \text{Å})\), respectively) are the shortest such distances.
observed in hypervalent germanium structures\(^2\), whereas the Ge—O(Tf) and Ge—O(ClO\(_3\)) bond lengths (3.02–3.35 Å) are, on the contrary, the longest. Thus, the structures under consideration are more or less close to TBP, where two carbon and halogen atoms are in the equatorial positions and the axial positions are occupied by the two coordinating oxygen atoms, and consequently they may be viewed as doubly-intramolecularly coordinated germacenium ions, or tight ion pairs. Finally, tetafluoroborate \(^458\) has a typical ionic structure, and the array of the Ge atom is a distorted TBP opened, as in iodides \(^455\) and \(^457\), toward the BF\(_4^-\) anion\(^896\).

Note that the electronic system of the Ge atom together with its coordination environment may be regarded as two hypervalent O—Ge—O and X—Ge—Y subsystems which interact only slightly with each other. The Ge—O distances depend only weakly on the size of the lactam ring, whereas a considerable variation (within about 0.30 Å) in the length of the near-ionic sixth Ge···O bond is discernable. For analysis of the extent of the deviation of the geometries of the hypervalent fragments in these complexes from the ideal octahedron by using the parameter \(\Delta\Omega\), see elsewhere\(^478\).

The shortening of one and the significant elongation of another pseudo-axial bond of the X—Ge—Y hypervalent fragment in the mixed bis-chelate complexes \((L^n)_2 Ge(X)Y\) promotes the dissociation of such compounds. As a result, their solutions in CH\(_2 Cl_2\) have a high electroconductivity as compared with \((L^n)_2 GeX_2\) (Table 64), testifying to the existence in solution of germacenium ions \([L^n)_2 Ge(X)]^+\) stabilized by intramolecular (intraionic) coordination.

Preliminary results of \(^1\)H DNMR spectroscopy investigation enable one to estimate the activation free energies for the polytopic rearrangement in \(^452\)a–c, \(^453\), \(^454\)a,b and \(^457\) as >22 kcal mol\(^{-1}\) (the coalescence temperature of the NCH\(_A\)HBGe signals in CDCl\(_3\) is >55°C). These values are significantly higher than those for dichloride \((L^n)_2 GeCl_2\) (10.6–13.6 kcal mol\(^{-1}\))\(^90\).

A series of germanium compounds \(^459\)a–c stabilized by 2,6-bis(dialkyaminomethyl)-4-(\(t\)-butyl)phenyl tridentate ligand was recently obtained (equation 78)\(^897\). Their Si analogues Si-\(^459\)a and Si-\(^459\)d (\(R = H,\ R^1 = Me,\ R^2 = CH=CH_2\)) were analogously prepared.

\(^a\)L\(_n\) is the \(n\)-membered bidentate lactamomethyl C,O-chelating ligand.

All the systems were studied by \(^1\)H, \(^{13}\)C, \(^{15}\)N and \(^{29}\)Si NMR spectroscopy in solution and \(\text{459b}\), which was also characterized by an X-ray crystallography, were found to be stable compounds possessing ionic nature. The geometry around the central Ge atom in \(\text{459b}\) is a distorted TBP. The Ge–N distances are essentially equal, with values of 2.31 Å and 2.36 Å indicating a symmetrical structure in the solid state. The NGeN angle is distorted from 180° toward 158.0° in a direction opposite to the Berry pseudorotation coordinate. The overall environment around the Ge atom resembles closely an S\(_N\)2-like transition state with a backside attack of the incoming nucleophile. This symmetrical and hypervalent structure is the prevailing one in CD\(_3\)OD and DMSO-d\(_6\) solution only at low temperatures. At higher temperatures, a complex exchange process takes place.
In conclusion, although the NMR evidence supports the presence of stable pentavalent and symmetrical species in solution of \(459a\) and \(459c\), there is still a probability for intramolecular identity exchange. In contrast, the studies of silicon-containing compounds Si-\(459a\) and Si-\(459d\), have virtually excluded the presence of pentavalent, symmetrical forms as stable species in solution\(^{897}\).

### B. Tin and Lead Complexes

#### 1. Intermolecular complexes

The complex \([\text{Me}_3\text{SnBr}_2][\text{Me}_3\text{Sn(HMPA)}_2]\) (41) in which both the cation and anion contain TBP tin atoms is the first representative of five-coordinated organotin cations, whose structures were proved by X-ray diffraction\(^{227}\). These are numerous examples of cation–anion complexes containing pentacoordinated triorganotin cations stabilized by intermolecular donor–acceptor interaction. Some geometrical parameters for selected cases of cationic species with \([\text{SnC}_3\text{O}_2]^+\) and \([\text{SnC}_3\text{N}_2]^+\) moieties characterized by X-ray data are given in Table 65. The tin atoms in these complexes have a near-TBP geometry with the two electronegative ligands in axial positions with OSnO and NSnN angles close to 180\(^\circ\). For example, in cation \([\text{Me}_3\text{Sn(H}_2\text{O})_2]^+\) (entry 3), the OSnO angle is 177.0\(^\circ\), the mean values of the Sn–O and Sn–C bond lengths are 2.295 and 2.110 Å, respectively, and the sum of the equatorial angles is 359.9\(^\circ\)\(^{899}\). Generally, the O–Sn and N–Sn distances are in the ranges 2.23–2.33 and 2.33–2.38 Å, respectively, significantly longer than the typical bond lengths of 2.12 and 2.15 Å for pentacoordinate organotin compounds\(^8\).

On the basis of NMR data\(^{887}\) an equilibrium including triorganotin cations is suggested between tetravalent and two solvated TBP structures in solution (equation 79).\(^\)\(^9\)

![Image of chemical structure](image)

\(R = \text{Bu, Ph}; X = \text{Cl, ClO}_4, \text{BF}_4; S = \text{CH}_2\text{Cl}_2, \text{Pyr, DMSO, HMPA}\)

The changes in tin coordination are associated with an upfield shift in the tin resonance of the order of 200 ppm and an increase in the Sn–C one-bond coupling of ca 160–200 Hz. Bipyramidal forms are favored if the solvent donicity is increased, including structures in which the solvent molecules occupy the two axial positions of the five-coordinate TBP.

A series of dimeric organotin cations \([\text{R}_2\text{SnOH(H}_2\text{O})_2]^{2+}\) (460) were synthesized from \(\text{R}_2\text{SnO}\) and \(\text{TfOH}\) (equation 80)\(^9\). The reaction proceeds with the participation of 1 equivalent of water, which is present, probably, in a trace amount in the MeCN solvent. The \(\text{H}_2\text{O}\) molecule in 460 can be readily replaced by HMPA to yield \([\text{R}_2\text{SnOH(HMPA)}]^{2+}\) (460d, \(R = n\)-Bu). The structures of 460 were investigated by single-crystal X-ray analysis and solid-state \(^{119}\text{Sn}\) NMR, and by \(^{119}\text{Sn}\) NMR spectra and electrical conductivity measurement in solution.

Compounds 460a and 460b possess cationic structures both in the solid state and in solution. The \(n\)-butyltin derivatives 460c and 460d dissociate also into ionic species in solution but are nonionic in the solid state and involve coordinating triflates, though the...

cTwo independent molecules in the unit cell.

bonding is very weak (Sn–O(Tf) 2.62 and 2.82 Å, respectively). The corresponding distances in ionic species with bulkier alkyl groups are 4.15–4.82 Å for 460a and 3.86–4.29 Å for 460b while the sums of the covalent radii and the van der Waals radii of Sn and O are 2.12 Å and 3.70 Å, respectively (Table 1). Additionally, the cationic character is reflected in the stronger coordination by H₂O molecules: Sn–O(H₂) 2.29 for 460a, 2.26 for 460b and 2.41 for 460c.

In contrast, the analogous t-butyltin halides, [(t-Bu)₃SnOH](X)₂ (X = Cl, Br)ʰ, and methyltin and t-butyltin nitrates, [Me₂SnOH(NO₃)]²⁻ and [(t-Bu)₂SnOH(NO₃)]²⁻, have a nonionic structure with hydroxyl bridges, and the halogen atoms and nitrate ligands are covalently bonded to tin. It is concluded that both bulky alkyl groups attached
to tin and electronegative ligands such as triflate are crucial for the generation of the cationic species\textsuperscript{912,913}.

The polymeric structure of \([(\text{Me}_2\text{Sn})_2(\text{OH})_3]^+\text{ClO}_4^-\) has been determined by X-ray analysis\textsuperscript{915}. The polymer consists of five-coordinate tin units with di- and mono-hydroxo bridging. The coordination geometry at tin is a distorted TBP with the two methyl groups and one \(\mu\)-hydroxo group in equatorial positions and the other two \(\mu\)-hydroxo groups in axial positions.

\end{array}]^{2+} 2\text{OTf}^{-}
\end{equation}

\(\text{(460a)} \text{ R = } \text{t-Bu}\\n\text{(460b)} \text{ R = } \text{CH}_2\text{CH(Ph)Et}\\n\text{(460c)} \text{ R = } \text{n-Bu}

2. Intramolecular complexes

The first few pentacoordinate cationic tin complexes 461\textsuperscript{916,917} and 462\textsuperscript{916} were discussed in an earlier review\textsuperscript{636}. Based on \(^1\text{H}, \quad^{13}\text{C}\) and \(^{119}\text{Sn}\) spectroscopic studies\textsuperscript{916} as well as on conductivity measurements\textsuperscript{916}, ionic structures for these complexes were suggested. In the case of bromide 461a\textsuperscript{917} an ionic structure was unambiguously proved by X-ray diffraction. More recently, the structure of the analogous chloride as a 1 : 1 double salt with tetraaqualithium bromide, namely \([\text{Me}_2\text{SnC}_6\text{H}_3(\text{CH}_2\text{NMe}_2)_2-2,6]^+\text{Cl}^- \cdot [\text{Li}(\text{H}_2\text{O})_4]^+\text{Br}^- (463)\), was reported\textsuperscript{918}.

![Diagram of the ionic structure of \([\text{Me}_2\text{SnC}_6\text{H}_3(\text{CH}_2\text{NMe}_2)_2-2,6]^+\text{Cl}^- \cdot [\text{Li}(\text{H}_2\text{O})_4]^+\text{Br}^- (463)\)](image)

\(\text{(461)} \text{ X = Cl, Br, I; R, R}^1 = \text{Me, neopentyl, Ph, p-Tol}\\n\text{(461a)} \text{ X = Br, R = R}^1 = \text{Me}

The five-coordinate triorganotin cation in 463 has a planar SnC\(_3\) girdle (\(\Sigma\text{CSnC} = 360^\circ\)) and a distorted trans-TBP geometry about tin with the nitrogen atoms in the axial positions at the NSnN angle of 152.7\(^\circ\). The N–Sn distances (2.36 and 2.45 Å) are somewhat shorter than those found in halides \(\text{Me}_2\text{PhN}\text{SnCl} (240a)\textsuperscript{656} (2.49 \text{ Å}), \text{MePhPhN}\text{SnBr}\)
16. Hypervalent compounds of organic germanium, tin and lead derivatives

(248a) (2.48 and 2.55 Å) and Ph₂Ph₅SnBr (242) (2.51 Å) (Section VII.A.1.c), which are molecular triorganotin compounds substituted by only one CH₂NMe₂ in the phenyl ring.

The reaction of dinuclear stannane 464 with [PtCl₂(COD)] (COD = cycloocta-1,5-diene) or Me₃SnCl led to methyl group transfer to platinum or tin, respectively, with formation of the cations 465a and 465b, differing in the counter anion (equation 81). These cations interact with the mononuclear hexacoordinate tetraorganotin compound Me₃Sn[C₆H₃(CH₂NMe₂)₂-2,6] to give the pentacoordinate cationic tin complexes {Me₂Sn[C₆H₃(CH₂NMe₂)₂-2,6]}²⁺ + 2X⁻ (X = Cl or Me₃SnCl₂).

An X-ray structure determination of 465b reveals that the central dimetalated aryl ligand system provides tridentate meridional NCN'-coordination to both tin centers. The N–Sn distances (2.392 and 2.395 Å) and the NSnN angles (152.0°) are close to those found for the triorganotin cation in salt 463.

In contrast to equation 81, the neutral five- and six-coordinate organotin derivatives, the heterocyclic compounds 427a, 427b, 428a, 428b and 431, containing the monoanionic O,C,O-coordinating ligand {4-t-Bu-2,6-[PO(OEt)₂]₂C₆H₂}⁻, were only isolated as end products by treatment of six-coordinate precursors {4-t-Bu-2,6-[PO(OEt)₂]₂C₆H₂}SnRR¹ (426a, 426b, 430) with HCl or X₂ (X = Br, I, see Section VII.B.2)¹⁴⁷,⁷⁶²,⁷⁶⁹. However, cationic tin species of type 429 are suggested as intermediates in these reactions. The isolation of the related hexafluorophosphate derivative {4-t-Bu-2,6-[PO(OPr-i)₂]₂C₆H₂}SnPh₂⁺PF₆⁻ supports the intermediacy of 429.
Only recently, an aliphatic analogue of the pentacoordinate cationic tin complexes 461, the triorganotin iodide derivative 466, was obtained (equation 82)\(^9\)\(^{18}\).

\[
\text{Ph}_2\text{Sn}[(\text{CH}_2)_3\text{NMe}_2]_2 + \text{I}_2 \xrightarrow{\text{CH}_2\text{Cl}_2 - \text{PhI}} \begin{array}{c}
\text{Me}_2\text{N} \\
\text{NMe}_2 \\
\text{Ph} \\
\text{Sn} \\
\end{array} \\
\text{I}^- \\
(82)
\]

\[
(466)
\]

According to an X-ray analysis, 466 consists of an intramolecularly coordinated triorganotin cation and iodide anion with the I⋯Sn separation at 4.457 Å, a distance slightly larger than the sum of van der Waals radii of Sn and I (Table 1). The array of the Sn atom is a slightly distorted TBP (the NSnN angle is 174.6°), opened, like in the cation–anion germanium iodide complexes 455, 457, and the tetrafluoroborate 458 (Section VIII.A), toward the anion (the CSnC angle is 131.7°). The N⋯Sn distances (2.392 and 2.401 Å) are close to those found for the triorganotin cation in the salt 465b, differing significantly from those in the closely related intramolecularly hexacoordinated triorganotin iodide [8-Me2N-1-C10H6]2SnIMe (2.53 and 3.10 Å)\(^9\)\(^{19}\).

Wrackmeyer and coworkers described a family of triorganotin and triorganolead cations, namely 467–469 (R, R1, R2 = Alk, Ph; L = 2-Pyr, CH2NMe2, CH=CHOMe, CH2SEt), stabilized by the asymmetric side-on coordination of the C≡C bond to the metal atom in alkynyhydrides. The cationic center in these zwitterionic compounds may be alternatively viewed as containing Sn formally five- or six-coordinate to carbon as shown, for example, in structures 467' and 468'. The nature of the stabilization of triorganotin cations, as well as the competition between intramolecular coordinating O–, S– or N–Sn bonds (functional substituent in L) and side-on π coordination to C≡C bonds in 469 is considered on the basis of comparison of X-ray data for compounds 469a–c and those for complexes 467a and 468a having no functional group.

\end{align*}
\]

This topic was discussed in more detail in other reviews\(^9,\)\(^53\).
IX. HEXACOORDINATE ANIONIC COMPOUNDS

A. Intermolecular Complexes

1. Germanium

Complexes of (trifluoromethyl)halogermanes with fluoride ions\textsuperscript{207,208,922–924} are discussed in Section IV.A.1. In the presence of KF the fluorides CF\textsubscript{3}GeF\textsubscript{3} and (CF\textsubscript{3})\textsubscript{2}GeF\textsubscript{2} are capable of forming anions 470 and 471, respectively. Tris- and tetrakis-CF\textsubscript{3} derivatives generally form the (CF\textsubscript{3})\textsubscript{n}GeF\textsubscript{5−n} \textsubscript{n}(n = 3, 4) adducts, although the excess of KF in aprotic solvents may lead to dianions 29 and 28 that are stable only in the total absence of moisture\textsuperscript{207,208}. According to \textsuperscript{19}F NMR spectra, all the dinegatively charged anions have octahedral structures with cis-configuration of CF\textsubscript{3} groups\textsuperscript{208}. The structure of 471 in the salt K\textsubscript{2}[CF\textsubscript{3})\textsubscript{2}GeF\textsubscript{4}] was confirmed by X-ray data\textsuperscript{207}. The Ge\textsuperscript{−}F bond lengths are 1.833 and 1.824 Å for equatorial and axial F atoms, respectively, while the Ge\textsuperscript{−}C distances are 2.041 Å.

The first representative of hexacoordinate germanium compounds with a GeF\textsubscript{5}C framework, the zwitterionic germanate 472, was recently synthesized (equation 83)\textsuperscript{925}.

\[
\begin{align*}
\text{(MeO)}\text{3GeCH}_2\text{N} & \quad \text{HF} \\
\text{NMe} & \\
\end{align*}
\]

(472)

A crystal structure determination of 472 \cdot H\textsubscript{2}O reveals a slightly distorted octahedral geometry about the germanium atom dominated by intermolecular N\textsuperscript{−}H\cdots F and O\textsuperscript{−}H\cdots F hydrogen bonds. The Ge\textsuperscript{−}C distances, 1.977 and 1.978 Å for two independent zwitterions in the unit cell, are similar to those obtained for anion 471\textsuperscript{207}. The Ge\textsuperscript{−}F distances in 472 \cdot H\textsubscript{2}O are 1.788–1.867 Å, longer than those obtained for the GeF\textsubscript{6}\textsuperscript{2−} anion (1.77 Å\textsuperscript{926} and 1.79 Å\textsuperscript{927}) but comparable to those reported for 471.

According to X-ray data, the GeCl\textsubscript{6}\textsuperscript{2−} anion in the salt [GeCl\textsubscript{6}][Ph\textsubscript{4}P]\textsubscript{2} described recently\textsuperscript{928} possesses a centrosymmetric octahedral structure. The Ge\textsuperscript{−}Cl bond lengths, 2.292 Å (average), are similar to those reported for the axial bonds in pentacoordinate GeCl\textsubscript{5}− ions, i.e. 2.25–2.32 Å\textsuperscript{306}, significantly longer than in the simple tetrahedral species GeCl\textsubscript{4} (2.113 Å, electron diffraction)\textsuperscript{9}. Distorted octahedral Ge(N\textsubscript{3})\textsubscript{6}\textsuperscript{2−} ions of C\textsubscript{1} symmetry were found in the complex [Ge(N\textsubscript{3})\textsubscript{6}][Na\textsubscript{2}(THF)\textsubscript{3}(Et\textsubscript{2}O)], including the interionic interactions between the anions and the solvated sodium cations with the average Ge\textsuperscript{−}N distance at 1.981 Å\textsuperscript{929}. However, the crystal structure of the salt [Ge(N\textsubscript{3})\textsubscript{6}][Na(PPh\textsubscript{3})\textsubscript{2}] reveals the presence of separated Ge(N\textsubscript{3})\textsubscript{6}\textsuperscript{2−} ions of S\textsubscript{2} symmetry enclosed by the voluminous counterions (the mean Ge\textsuperscript{−}N bond length is 1.974 Å).
2. Tin and lead

Attempts to prepare stable six-coordinate adducts like \([\text{Ph}_3\text{SnX}_2 \cdot \text{B}]^−\) or \([\text{Ph}_3\text{SnX}_3]^2−\) from the reactions of \(\text{Ph}_3\text{SnF}_2^−\) or \(\text{Ph}_3\text{SnFCl}^−\) with HMPA, DMSO, \(\text{F}^−\) and \(\text{Cl}^−\), as well as from \(\text{Ph}_3\text{SnCl}\) with an excess of \(\text{Cl}^−\) and \(\text{Br}^−\), were unsuccessful, although the presence of such anions in aprotic solution was detected by NMR spectroscopy. In contrast, rather stable mono- and dianions containing two, one or no organic groups at tin are known. NMR data are given elsewhere.

As for monoanions, the crystal structures of the only diorganotin derivative \(\text{MeSnMeClCl}\), two mono-organotin complexes \(\text{MeSnPyrX}^−\) \((\text{X} = \text{Cl}, \text{R} = \text{Et})\) \((\text{474a})\) and \(\text{MeSnPyrX}^−\) \((\text{X} = \text{Br}, \text{R} = \text{Bu})\) \((\text{474b})\), and a number of anions of the type \(\text{DSnCl}^−\) \((\text{D} = \text{MeCN}, \text{H}_2\text{O}, \text{THF})\) \((\text{475})\) have been described. Selected structural parameters for these compounds are given in Table 66.

\[
\begin{align*}
\text{Cl}_2\text{MeSnMeCl} & \quad [\text{HT}]^{2+}, \text{Cl}^− \quad \text{(473)} \\
[\text{X}] & \quad \text{Sn} \quad \text{X} \quad \text{PyrH}^+ \quad \text{(474a)} \text{ X} = \text{Cl}, \text{R} = \text{Et} \\
[\text{X}] & \quad \text{Sn} \quad \text{X} \quad \text{Pyr} \quad \text{(474B)} \text{ X} = \text{Br}, \text{R} = \text{Bu} \\
\text{Cl}_2\text{D} & \quad \text{Sn} \quad \text{Cl} \quad \text{(475)} \text{D} = \text{MeCN}, \text{H}_2\text{O}, \text{THF}
\end{align*}
\]

Aqua-chloro complexes, \(\text{473}\) and \([\text{Ph}_3\text{SnCl}_4][\text{HT}]\text{H}_2\text{O}\) \((\text{476})\) \((\text{T} = \text{thiamine})\), were recently obtained by the reaction of \(\text{TCI} \cdot \text{HCl}\) (vitamin \(\text{B}_1\) hydrochloride, \(\text{HT}^{2+}2\text{Cl}^−\)) with \(\text{Me}_2\text{SnCl}_2\) or \(\text{Ph}_2\text{SnCl}_2\), respectively, in 9 : 1 ethanol—water. In the anion of \(\text{470}\) (Table 66, entry 1), the tin atom coordinates to two trans carbon atoms of the methyl groups, three \(\text{Cl}\) atoms and the \(\text{O}\) atom of a water molecule in a distorted octahedral arrangement (the \(\text{CSnC}\) angle of 165.8° is the most distorted geometrical parameter). The \(\text{O}−\text{Sn}\) bond, 2.418 Å, is longer than in neutral aqua-chloro complexes \(\text{Me}_2\text{Sn}(\text{H}_2\text{O})\text{Cl}_2\) (2.235 Å) and \(\text{Me}_2\text{Sn}(\text{H}_2\text{O})\text{Cl}_2\) (2.407 Å). Comparison of the structural parameters of \(\text{Me}_2\text{Sn}(\text{H}_2\text{O})\text{Cl}_3^−\) with those of \(\text{Me}_2\text{SnCl}_3^−\) shows that coordination to water does not significantly change the \(\text{Sn}−\text{Cl}\) bond distances, but does lengthen the \(\text{Sn}−\text{C}\) bond distances and widen the \(\text{CSnC}\) angle from 140 to 165.8°.

In anions of \(\text{474a}\) and \(\text{474b}\) \((\text{entries 2 and 3})\), the pyridine molecule is trans to the alkyl group, and there is nonequivalence of the \(\text{Sn}−\text{Cl}\) and \(\text{Sn}−\text{Br}\) distances owing to hydrogen bonding with the pyridinium cation. A cis-shortening of the mean values of the \(\text{Sn}−\text{Cl}\) and \(\text{Sn}−\text{Br}\) distances by the influence of the alkyl group was noted, as well as an equal \(\text{Sn}−\text{C}\) and \(\text{Sn}−\text{N}\) bond lengthening on going from chloride \(\text{474a}\) to bromide \(\text{474B}\).

A special feature of anions \(\text{475}\) in complexes with different counterions \((\text{entries 4}−\text{16})\) is a lengthening of the \(\text{N}−\text{Sn}\) or \(\text{O}−\text{Sn}\) coordinative bonds up to 2.28–2.32 and 2.17–2.27 Å, respectively, compared to the mean values for penta- and hexacoordinated tin compounds (2.12 and 2.15 Å). Accordingly, the \(\text{Sn}−\text{Cl}\) bond length trans to \(\text{N}\) or \(\text{O}\), at 2.36–2.42 Å, is somewhat shorter than that in hypervalent compounds (2.45 Å), and is generally shorter in comparison with the other \(\text{Sn}−\text{Cl}\) bonds in these complexes.

The reaction of butyltin trichloride with 1-(2-methyl-2,3-dihydrobenzotriazol-2-yl)-propan-2-one gives an organotin complex that was formulated as containing the \([\text{BuSn(OH)}\text{Cl}_3]^2−\) anion. However, a reinvestigation of the crystal structure of this complex reveals a neutral hydroxyl-bridged aqua-butyldichlorotin hydroxide dimer that is linked to four 2-methylbenzothiazole molecules by short hydrogen bonds.

fTwo independent anions.

The chloro dianion in the complex [Me₆Sn₃Cl₈][L]₂ (477, L = dibenzotetrathiafulvalene) can be also considered as the adduct Me₂SnCl₂·2Me₂SnCl₃−. In this dianion the internal tin atom, Sn², has a near-octahedral configuration with a C−Sn−C angle of 177.9°, while the coordination environment of the two terminal tin atoms, Sn¹ and Sn³, can be described as a distorted octahedron (the C−Sn−C angle is about 160°). Consequently, there are three types of Sn−Cl bonds distinguished by their length. The four terminal Sn¹−Cl and Sn¹−Cl bonds, at 2.42−2.46 Å, are the shortest, while the four bridged Sn²−Cl bonds are longer (2.63−2.68 Å). Finally, the four other bridged Sn¹−Cl and Sn³−Cl bonds of 2.96−3.10 Å are longest among those detected for hypervalent organotin chlorides, but yet significantly shorter than the sum of van der Waals radii of the tin and chlorine atoms.
Reaction of diorganotin dihalides with halide ions, which can lead to the formation of either pentacoordinate trihalodiorganostannates $R_2SnX_3^{2-}$ or hexacoordinate tetrahalodiorganostannates $R_2SnX_4^{2-}$, was discussed in Section IV.A.4. As noted, the $[Ph_2SnCl_4]^{2-}$ anion is formed from the disproportionation reaction of $Ph_2SnCl_3^{2-}$ (equation 10, Section IV.A.4) rather than by addition of chloride ion to the latter281.

Table 67 presents selected X-ray data for anions $R_2SnX_4^{2-}$ (478), $RSnX_5^{2-}$ (479) and $PhPbCl_5^{2-}$ (480) in hexacoordinate anionic tin and lead complexes. Most of the $R_2SnX_4^{2-}$ anions generally have a centrosymmetric trans-octahedral structure and $X = Cl$. For the other halides, only the crystal structures of $[Me_2SnBr_4](Et_4N)^{2-}$, $[Ph_2SnBr_4](NHC_5H_5)^{2-}$ and $[Me_2SnF_4](NH_4)^{2-}$ have been reported. It is significant that the latter crystallizes as an anhydrous salt, probably because all its F atoms are already involved in hydrogen bonds278, while $K_2[Me_2SnF_4]$ crystallizes as a dihydrate from aqueous solutions967.

Among $L_2SnX_4$ complexes, the salts of anions $R_2SnX_4^{2-}$ possess the longest $Sn-X$ distances and the largest Mössbauer quadrupole splitting values and they were used for the correlation between both parameters968,969. The average $Sn-Hal$ distance (2.127 Å in $Me_2SnF_4^{2-}$ (entry 1), 2.600–2.625 Å in $Me_2SnCl_4^{2-}$ (entries 2–8) and 2.768 Å in $Me_2SnBr_4^{2-}$ (entry 17) is significantly longer than for the corresponding octahedral $SnHal_6^{2-}$ (Table 67), consistent with the concept that the strong donor methyl groups weaken the $Sn-Hal$ bonds278. This is also in agreement with the isovalent rehybridization concept970a, since the $Sn$ atom will concentrate larger s character into the hybrid orbitals directed toward the less electronegative methyl groups, and larger p character in the hybrid orbitals directed to Hal.

The $Me_2SnCl_4^{2-}$ anion has generally a centrosymmetric trans-octahedral structure. The observed differences in the $Sn-Cl$ bond lengths (entries 2–8) can be ascribed mainly to hydrogen-bonding effects causing elongation of these bonds. Thus, the shortest $Sn-Cl$ distances are found for the tetraathiafulvalenium compound (entry 2) in which no H-bonds are present288. In the case of 8-methylaminoquinolinium derivative (entry 9), all the $Sn-Cl$ distances are different (2.442, 2.461, 2.894 and 3.098 Å)953. The two long $Sn-Cl$ bonds are trans to the short ones and their Cl atoms are H-bonded to the N−H groups of the cations. The $Sn-C$ bonds are bent away from the short $Sn-Cl$ bonds so that the

$^c$Centrosymmetric anion.

$^d$Two crystallographically independent anions in the unit cell.

$^e$Average value.

$^f$ClSnClicis).

$^g$Sn–Cl···H(N).

$^h$Trans to carbon.

$^i$Cis to carbon (average).

$^j$CSnHal(trans).
As the Cl\(^-\) ions are removed, the remaining Sn–Cl bonds get shorter and the CSnC angle becomes narrower\textsuperscript{953}.

The average Sn–Cl distance in anions R\(_2\)SnCl\(_4\)\(^{2-}\) is correlated with the Lewis acidity of the diorganothiotin moiety. The average Sn–Cl bond distances in the Vin\(_2\)Sn (2.593 Å) complexes and Pb\(_2\)Sn (2.583 Å) (entries 11 and 13) are practically equivalent, as both involve C\(_{sp2}\) atoms, and are shorter than the distance found in the Me\(_2\)Sn compounds (e.g. 2.628, entry 5).

There are two kinds of Pb\(_2\)SnCl\(_4\)\(^{2-}\) anions in 476, one placed between two cations with its phenyl groups stacking over their pyrimidine rings, and the other without a close relationship to any cation. The two Sn atoms lie on a crystallographic inversion center\textsuperscript{930}.

A comparison of the six-coordinate and five-coordinate anions, Me\(_2\)SnBr\(_4\)\(^{2-}\) and Me\(_2\)SnBr\(_3\)\(^-\), demonstrates Sn–Br distances in the order Sn–Br (oct) (2.768 Å) > Sn–Br (ax) (2.734 Å) > Sn–Br (eq) (2.498 Å)\textsuperscript{270}. The latter distance is of the same order of magnitude as that in tetracoordinate compounds (2.49 Å)\textsuperscript{9}.

High level \textit{ab initio} SCF MO calculations showed that trans-[R\(_2\)SnX\(_4\)]\(^{2-}\) anions are stable with respect to their cis-isomers by ca 19 kcal mol\(^{-1}\) (R = Me, Et; X = Cl)\textsuperscript{270}. While the gas-phase formation of pentacoordinate [R\(_2\)SnX\(_3\)]\(^-\) anions from R\(_2\)SnX\(_2\) and X\(^-\) is an exothermic process, hexacoordinate [R\(_2\)SnX\(_4\)]\(^{2-}\) anions are unstable in the gas phase toward dissociation into [R\(_2\)SnX\(_3\)]\(^-\) and X\(^-\) (R = Me, Et; X = Hal). For octahedral trans-[R\(_2\)SnX\(_4\)]\(^{2-}\) anions, the Sn–X bonds are even longer (by ca 3%) than the axial Sn–X bond in the TBP [R\(_2\)SnX\(_3\)]\(^-\) anions. Moreover, for cis-[R\(_2\)SnCl\(_4\)]\(^{2-}\) anions (R = Me, Et), the Sn–Cl bonds cis to the R groups are longer than the trans bonds, in line with the \textit{cis} weakening effect of the R groups previously found experimentally\textsuperscript{25,970b}.

Reaction of KF with RSnCl\(_3\) in water leads to the formation of water-soluble complexes of the type K\(_2\)[RSnF\(_5\)]\textsuperscript{296,971a}. Similarly, and in contrast to the reaction between halide ions and X\(_3\)Sn(CH\(_2\))\(_n\)SnX\(_3\) (X = Cl, Br; n = 1, 3, 4, 8), which yield five-coordinate dinuclear 1:2 adducts (equation 13, Section IV.A.5), the hexachloride Cl\(_3\)Sn(CH\(_2\))\(_3\)SnCl\(_3\) reacts with an excess of KF in water to give the dianionic species K\(_2\)[F\(_3\)Sn(CH\(_2\))\(_3\)SnF\(_5\)] (481) in solution. The \(^{119}\)Sn and \(^{19}\)F NMR data indicate that the tin atoms in both K\(_2\)[BuSnF\(_5\)] and 481 are six-coordinate (\(\delta^{119}\)Sn = 625.1 and = 615.7 ppm, respectively)\textsuperscript{296}.

X-ray studies of hexacoordinate RSnX\(_5\)\(^{2-}\) anions of the type 479 (entries 21–26)\textsuperscript{295,907,950–961} showed octahedral geometry for all the tin atoms with the shorter Sn–X distances (2.42–2.47 Å for X = Cl, 2.56 Å for X = Br) for those trans to the Sn–C bond. The mean values of the remaining four Sn–X distances are in the range of 2.48–2.52 Å (X = Cl) and 2.70 Å (X = Br). These data were used as evidence of \textit{trans}-strengthening in octahedral tin chlorine- and bromine-containing complexes\textsuperscript{959}. A similar geometry is found for the hexacoordinate PhPbCl\(_5\)\(^{2-}\) (480, entry 27)\textsuperscript{960} with a Pb–Cl distance \textit{trans} to the phenyl ligand of 2.46 Å, which is significantly shorter than the other four Pb–Cl distances (2.60–2.68 Å). Earlier examples of complexes with this anion can be found elsewhere\textsuperscript{305}.

The reaction of the difluoride [Me\(_2\)N(CH\(_2\))\(_3\)]\(_2\)SnF\(_2\) with an excess of Bu\(_4\)NF · 3H\(_2\)O in CH\(_2\)Cl\(_2\) solution lead to the zwitterionic compounds 482 and 483, depending on the concentration of reactants\textsuperscript{971b}. It is suggested that attack of fluoride ions at tin which intramolecularly coordinated in the precursor difluoride [Me\(_2\)N(CH\(_2\))\(_3\)]\(_2\)SnF\(_2\) results in Sn–bond dissociation and enhancement of the nucleophilicity of the 3-dimethylaminopropyl nitrogens by the hypercoordinate C\(_2\)SnF\(_3\)\(^-\) and C\(_2\)SnF\(_4\)\(^{2-}\) configurated tin centers. Consequently, the reaction of tertiary amino groups with dichloromethane is facilitated.
An X-ray diffraction of 483, which is formed in more concentrated solutions, reveals a near-ideal octahedral structure with FSnF\(\text{trans}\) and CSnC angles of 180° and Sn–F bond lengths in the range 2.06–2.11 Å, which is above the standard value for tetracoordinate compounds (1.96 Å)\(^9\) and Sn\(\text{F}_6\)^2– anion (1.955 Å)\(^{278}\), and is very close to those in Me\(_2\)Sn\(\text{F}_4\)^2– (ca 2.13 Å)\(^{278}\).

**B. Intramolecular Complexes**

A number of anionic hexacoordinate O,O- and S,S-chelates have been reported. Among them, the acetylacetonate \([\text{Cl}_4\text{Sn(MeCOCHCOMe)}][\text{Et}_3\text{NH}]\) (484)\(^{972}\) and oxalato ditin species \([\text{Cl}_4\text{Sn(OOCCOO)}\text{SnCl}_4][\text{Et}_4\text{N}]\)\(^{2973}\) are rare examples of mono-chelate anionic complexes. A crystallographic study of 484 showed a near-octahedral geometry at tin with two axial (ClSnCl 172.3°, Sn–Cl 2.400 and 2.445 Å) and equatorial (ClSnCl 97.1°, Sn–Cl 2.370 Å) chlorine atoms, as well as two equatorial oxygen atoms (OSnO 87.5°, Sn–O 2.093 Å).

Another example for mono-chelate complexes investigated for their antitumour activity\(^{857}\) consists of tetraethylammonium halide adducts 485 (X = Hal, R = Alk, Ar) containing O,N,O-tridentate dianionic ligand.

Rare representatives of anionic hexacoordinate organotin chelates are the bisoxalato complexes 486a\(^{974}\) and 486b\(^{975}\). According to an X-ray study, the anion in 486a adopts
a skew-trapezoidal geometry owing to anisobidentate chelation by the oxalato groups (Sn–O = 2.110, 2.112, 2.363 and 2.348 Å; CSnC 146.7°). In the diphenyl analogue \( \text{Sn} \) which was unexpectedly isolated from the disproportionation of the precursor oxalato-riphenylstannate, the tin atom exists in a distorted octahedral environment with somewhat different but closer O–Sn distances (2.121 and 2.184 Å) than in the anion of \( \text{Sn} \), and two cis-phenyl groups (CSnC 106.0°).

In the related dimethyl analogue, the aqua complex \( [\text{Me}_2\text{Sn}(\text{C}_2\text{O}_4)_2(\text{H}_2\text{O})][(c-\text{C}_6\text{H}_{11})_2\text{NH}_2]_2 \)\(^{976}\), the coordination number of tin is expanded from six to seven due to the coordinated water molecule (Sn–O(\( \text{H}_2 \)) = 2.428 Å). The Sn atom is chelated by two isobidentate oxalato groups (O–Sn = 2.24–2.32 Å) and exists in a \( \text{trans} - \text{C}_2\text{SnO}_5 \) pentagonal–bipyramidal environment (CSnC 173.5°). A similar structure was earlier found for \( [\text{Me}_2\text{Sn}(\text{OAc})_3][\text{NMe}_4], \) in which the tin atom is chelated by two anisobidentate acetato groups (O–Sn 2.270, 2.271 Å and 2.524, 2.520 Å) and one monodentate acetato group (O–Sn 2.113 Å, the second O···Sn separation is 3.334 Å)\(^{29}\).

Unlike organogermanium and organotin derivatives, bis- and tris-chelates without M–C bonds have been known for a long time. Tris(2,3-butanediolato) dianionic germanium complexes were used in reactions with organometallic reagents for the preparation of organogermanes\(^{977,978}\). X-ray studies of the hexacoordinate anions, trisoxalate \( \text{Ge(OCCOO)}_3 \)\(^{2−} \)\(^{979,980}\) and trisoxalate \( \text{Ge}(1,2-\text{OC}_6\text{H}_4\text{O})_3 \)\(^{2−} \)\(^{981,982}\), reveal the germanium center to be octahedrally coordinated by three 1,2-diolato ligands with OGeO angles in the ranges of 84°–86° and 173.0–175.4°, and the Ge–O bond lengths in the range 1.84–1.90 Å. A similar geometry is found for their tin analogues, tris(1,2-OC\(_6\)H\(_4\)O\(_3\))\(^{2−} \), (Sn4(NO\(_2\)-1,2-OC\(_6\)H\(_4\)O)\(_3\))\(^{2−} \), Sn(1,2-OC\(_6\)Cl\(_2\)O)\(_3\))\(^{2−} \) and the catecholthiolate Sn(1,2-OC\(_6\)H\(_4\)S)\(_3\))\(^{2−} \). The structure of the bis-chelate bis(tetramethylammonium) bis(citrato)tin containing O,O,O-dianionic tridentate ligand was also established\(^{985}\).

Hexacoordinate 1,2-dithiolato complexes, the bis-MN derivatives, e.g. \([\text{MNT})_2 \)\( \text{Sn(OH)}_2[\text{Et}_4\text{N}]_2 \)\(^{986}\), and bis-DMIT compounds, \( \text{Sn(OH)}_2[\text{Et}_4\text{N}]_2 \)\(^{987}\), as well as tris-chelates containing DMIT, \( \text{Sn(OH)}_2[\text{Et}_4\text{N}]_2 \)\(^{987}\), and DSIT, \( [\text{Sn(DSIT)}_3][\text{R}_4\text{N}]_2 \)\(^{987}\), \( [\text{Sn(DSIT)}_3][\text{R}_4\text{N}]_2 \)\(^{987}\), \( [\text{Sn(DSIT)}_3][\text{R}_4\text{N}]_2 \)\(^{987}\), \( [\text{Sn(DSIT)}_3][\text{R}_4\text{N}]_2 \)\(^{987}\), \( [\text{Sn(DSIT)}_3][\text{R}_4\text{N}]_2 \)\(^{987}\), \( [\text{Sn(DSIT)}_3][\text{R}_4\text{N}]_2 \)\(^{987}\), were reported. Dihalides \( \text{Sn}(1,2-\text{OC}_6\text{H}_4\text{O})_3 \)\(^{2−} \), \( \text{Sn}(4-\text{NO}_2-1,2-\text{OC}_6\text{H}_4\text{O})_3 \)\(^{2−} \), \( \text{Sn}(1,2-\text{OC}_6\text{Cl}_2\text{O})_3 \)\(^{2−} \) and the catecholthiolate \( \text{Sn}(1,2-\text{OC}_6\text{H}_4\text{S})_3 \)\(^{2−} \) were prepared from \( [\text{Zn(DMIT)}_2][\text{Bu}_4\text{N}]_2 \), SnX\(_4\) in the presence of Bu\(_4\)Nb. Note that while the bis-chelate dianions, \( [\text{Sn(DMIT)}_2\text{X}_2]^{-} \) (X = Br, I), were synthesized\(^{987}\), the corresponding fluoride and chloride compounds were yet to be isolated\(^{988}\). Isolation of the tris(DMIT)stannate salts was achieved from reactions of SnCl\(_4\) with \([\text{Zn(DMIT)}_2][\text{M}]_2 \), from reaction mixtures containing \( [\text{Sn(DMIT)}_2\text{X}_2][\text{M}]_2 \) (X = Br, I) and fluoride ion and from the reactions of SnCl\(_2\) with Sn(OAc)\(_4\) in the presence of MX (X = F, Br or I). The related DMIO and DSIT derivatives \( \text{Sn(OH)}_2[\text{Et}_4\text{N}]_2 \)\(^{987}\), and \( \text{Sn(OH)}_2[\text{Et}_4\text{N}]_2 \)\(^{987}\), were obtained by the reaction of tin(IV) compounds with dithiolato and dielenolate precursors\(^{988}\).

Crystal structure determinations of the bis- and tris-(dithiolato)stannate salts \( \text{Sn(OH)}_2[\text{Et}_4\text{N}]_2 \)\(^{987}\), \( \text{Sn(OH)}_2[\text{Et}_4\text{N}]_2 \)\(^{987}\), \( \text{Sn(OH)}_2[\text{Et}_4\text{N}]_2 \)\(^{987}\), and \( \text{Sn(OH)}_2[\text{Et}_4\text{N}]_2 \)\(^{987}\), revealed an essentially octahedral geometry about tin with chelate bite angles of 80.7–87.4°, Sn–S distances of 2.52–2.57 Å and \( \text{trans} \) SSnS angles from 162.3 to 174.6°. For \( \text{Sn} \) containing cis-iiodide ligands, the Sn–I bond lengths are 2.724 and 2.727 Å with an ISnI angle of 90.1°. The Sn–I values compare with those found for tetracoordinate, tetrahedral R\(_3\)SnI compounds. The differences between the values of the Sn–S bond lengths \( \text{trans} \) to sulfur (2.520 and 2.539 Å) and \( \text{trans} \) to iodine (2.554 and 2.566 Å) are relatively small.

A statistical analysis, carried out on the crystal structure data for the tris-chelates \( \text{Sn(OH)}_2[\text{Et}_4\text{N}]_2 \)\(^{987}\), indicated that the most critical factors in controlling the overall shape of the dianion were the distances of the Sn atom from the dithiolate ligand planes.
The $^{119}$Sn NMR spectra of the 1,2-dithiolato complexes discussed above in various solvents indicate ionized species with anions containing six-coordinate tin atoms. The $\delta^{119}$Sn NMR values are about $-248$ ppm for $[\text{Sn(DMIT)}_2\text{X}_2]^{2-}$, $-249 \pm 2$ ppm for $[\text{Sn(DMIT)}_3]^{2-}$, $278 \pm 5$ for $[\text{Sn(DMIO)}_3]^{2-}$ and $-237$ for a single $[\text{Sn(DSIT)}_3]^{2-}$ complex$^{987,988}$; these values are in the region for six-coordinate tin species.

X. HEXACOORDINATE NEUTRAL COMPOUNDS

Some neutral complexes, in which the central atom is hexacoordinate due to intermolecular or/and intramolecular coordination, have been described. The presence of the electronegative substituents is essential for the formation of such complexes, and their stability generally increases in the sequence: Ge < Sn < Pb.

A. Complexes with Intermolecular Coordination

Hexacoordinate neutral complexes can include either two monodentate or one bidentate donor ligand. Formally, the latter is a chelate complex; however, the presence of two intermolecular coordinate bonds enables one to consider such a ligand in this section.

1. Germanium

A clearly pronounced acceptor ability of the tetravalent organogermanes $R_n\text{GeCl}_{4-n}$ ($n = 1, 3, R = \text{Ph}; n = 2, R = \text{Me}$) toward N-, P- and O-donor molecules was deduced from calorimetric titration. $\text{Me}_2\text{GeCl}_2$ forms $1:2$ complexes with $\text{Bu}_3\text{N}^{54}$, but, as well as
Ph$_2$GeCl$_2$\textsuperscript{53}, it does not react with 2,2$'$-bipyridine, 2-methylpyridine and with O- and P-donors. The reaction of diorganodichlorogermanes with 1,10-phenanthroline (Phen) results in hexacoordinate adducts R$_2$GeCl$_2$·Phen (R = n-Bu, Ph), but their physical-chemical characteristics were not reported, with the exception of their melting points\textsuperscript{58}. Phenyltrichlorogermane forms 1 : 2 adducts with all the monodentate ligands investigated and 1 : 1 complexes with bidentate ligands. Several adducts were isolated, but their structures were not studied in detail.

The composition and structure of the adducts of trifluoromethylhalogermanes and (CF$_3$)$_4$Ge with N- and O-donating ligands have been studied\textsuperscript{922,989}. Trifluoromethylhalogermanes easily form 1 : 1 and 1 : 2 complexes with amines and ammonia. (CF$_3$)$_4$Ge gives adducts\textsuperscript{491} with ammonia and primary amines (equation 84).

\[
(CF_3)_4Ge + nNH_2R \rightarrow (CF_3)_4(\text{GeNH}_2R)_n
\]

\((491)\ R = \text{H}, \ n = 2, 3\)

\((491)\ R = \text{Me}, \ n = 1, 2\)

Secondary and tertiary amines, pyridine, aniline and 1,2-diaminobenzene do not react with (CF$_3$)$_4$Ge due to steric factors. Complexes of the type\textsuperscript{491} slowly decompose on storage to afford cyclic oligomers such as [(CF$_3$)$_2$GeNR]$_3$\textsuperscript{989}. Hexacoordination of the germanium in\textsuperscript{491} and analogous complexes with N- and O-donors (CF$_3$)$_4$GeL$_2$ (L = NH$_3$, MeNH$_2$, DMSO, Me$_2$P(O)H was established by $^1$H NMR, IR and Raman spectroscopy\textsuperscript{989}.

Structurally characterized GeX$_4$D$_2$ systems possess cis-isomers in the case of bidentate ligands as for\textsuperscript{492} and trans-isomers for monodentate bis-ligands (Table 68). The structure of the tetrachlorobis(4-methylpyridine)germanium\textsuperscript{993}, tetrabromobis(4-methylpyridine)germanium, tetrabromobis(3,4-dimethylpyridine)germanium\textsuperscript{994} and\textsuperscript{493} is octahedron with two aromatic nitrogen- and arsenic-donor ligands in trans-axial positions.

The structures of germanium complexes\textsuperscript{494a,995,494b,996,495a,997 and 495b,998} show that the central Ge atom has an octahedral structure with two bidentate deprotonated catechol moiety in equatorial positions.

Complex\textsuperscript{494a} has an ideal octahedral structure (O $\rightarrow$ Ge $\leftarrow$ O 180°), and the distance between the Ge and the equatorial plane is 0.0 Å. Among the three types of Ge–O bonds,

| TABLE 68. Selected structural data for GeX$_4$-D$_2$ complexes |
|------------------|--------|--------|--------|--------|--------|
|                  | X      | D      | D → Ge | Ge–X  | D → Sn ← D | Reference |
| ![Diagram](image) | ![Diagram](image) | 2.023  | 1.756(eq) | 79.3  | 990       |
| ![Diagram](image) | ![Diagram](image) | 2.029  | 1.777(ax) |        |           |
| ![Diagram](image) | ![Diagram](image) | 2.472  | 2.341    | 180.0 | 991       |
| ![Diagram](image) | ![Diagram](image) | 2.307  |          |        |           |
| ![Diagram](image) | ![Diagram](image) | 2.112  | 2.446    | 180.0 | 992       |
| ![Diagram](image) | ![Diagram](image) | 2.307  |          |        |           |
the bond lengths for the aqua oxygens (O → Ge 1.949 Å) are larger than those for the carboxylate oxygens (1.817 and 1.866 Å). The methanol adduct 495a has a slightly distorted octahedral structure with two molecules of methanol in axial positions. The O → Ge bond lengths (1.994 Å) for the methanol oxygens are longer than those for the catechol oxygens (1.823 and 1.850 Å) resulting from the stronger bonding to the aryloxide ligands.

73Ge chemical shifts for a series of hexacoordinated organogermanium GeX4D2 complexes (X = Cl, NCS, D2 = Bipy, Phen), as well as for GeBr4 · Bipy or GeI4 · Bipy complexes, were observed. A dramatic upfield 73Ge NMR shift for hexacoordinated organogermanium complexes GeCl₄(NCS)₄−n · D₂ (D₂ = Bipy and Phen) is associated with a change from tetracoordinated Ge to the hexacoordinated state (Table 69). The difference in the 73Ge chemical shifts, for example, for D₂ = Bipy (∆δ = −334.6 ppm) and for D₂ = Phen (−351.3 ppm) suggests the formation of a stronger complex. A large (50–57 ppm) upfield shift of the 15N resonances of Bipy in the complexes with respect to the free ligand (δ¹⁵N = −73.1 ppm in DMSO-d₆) is consistent with the involvement of the nitrogen lone pair in the N → Ge bond formation.

2. Tin

a. $XR_3Sn \cdot D_2$ systems. For this type of triorganotin complexes a second electronegative substituent $X$ for hypervalent bonding is absent and this does not promote formation of the hexacoordinate state. A rare example is the triphenyltin derivative $496^{1000}$, where the coordinate $N^1 \rightarrow Sn$ bond trans to oxygen (2.395 Å) is shorter than that trans to Ph (2.602 Å). The deviation from linearity in the former hypervalent bonding, ($N^1 \rightarrow Sn–O 158.8^\circ$), as compared to the latter, ($N^2 \rightarrow Sn–C 176.4^\circ$), is due to the additional intramolecular $O \cdot \cdot \cdot Sn$ (3.401 Å) contact$^{1000}$.

b. $X_2R_2Sn \cdot D_2$ systems. In recent years there has been increasing interest in the synthesis and structural study of octahedral diorganotin dihalide complexes, $R_2SnHal_2 \cdot D_2$, owing to their antitumour activity$^{280}$. Attempts to correlate structural data and antitumour activity have concluded that biologically active complexes have Sn–N bond lengths of $\geq 2.4$ Å, suggesting that dissociation of ligands is an important step in their mechanism of action. In principle, these types of diorganotin complexes can exist in five forms of geometrical isomers as shown below. The most widespread and representative from X-ray data are two isomers: (cis-D, trans-R) and all-trans.

```
cis-D trans-R
```

```
cis-D, trans-X
```

```
cis-D, trans-X
```

```
cis-D, trans-X
```

```
cis-D, trans-X
```

The most electronegative substituent $X$ should be placed, as a rule, in a trans-position to the coordination bond according to a linear hypervalent $D \rightarrow M–X$ bonding, i.e. the structure of octahedral $MR_2X_2 \cdot D_2$-type complexes assumes two linear $D \rightarrow M–X$ fragments with a cis-arrangement for $D$ and $X$ (cis-D, trans-R). Two linear fragments with organic substituents $D \rightarrow M–C$ (cis-D, trans-X), as well as less symmetrical structures (all-cis) were not observed experimentally. In some cases the donor fragments $D$ are in a trans-arrangement (trans-D), for which (all-trans) octahedral structures are mainly found, while a configuration with two linear $X–M–C$ fragments (trans-D, cis-X, R) is rare.

The difference in energies of cis- and trans-D isomers seems to be insignificant, in accordance with the simultaneous presence of both isomers in $Et_2SnCl_2(Ph_3PO)_2^{1001}$. In solution, the establishment of cis/trans-D equilibria in hexacoordinate tin complexes is generally fast on the $^1H$ NMR time scale. A rare observation of different isomers of neutral octahedral diorganotin compounds in solution was described$^{1002}$. This is somewhat surprising, but may be traced to the usually poor solubility of hexacoordinate organotin compounds, making low-temperature NMR studies difficult if not impossible.
16. Hypervalent compounds of organic germanium, tin and lead derivatives

i. Octahedral complexes with cis-D (trans-R) structure. The most important structural data of cis-SnR2X2 · D2 complexes with N,N-coordinating ligands are collected in Tables 70 and 71.

The adduct Me2SnBr2 · (MeCONMe2)_2 exists in a variety of structural types, in which the Sn atom can be, in particular, hexacoordinated. In this case, the preferred solid-state molecular structure of the central tin atom is cis-dibromo-trans-dimethyl. The structures of hexacoordinate ditin adducts 497, 498, 355 and 499 have also been reported.

The dihalide cis-SnR2X2 · D2 complexes with monodentate O- and S-donor ligands (e.g. DMSO, DMF) have been studied extensively (Table 72). In all cases, the tin atoms exhibit a distorted octahedral geometry. The degree of distortion becomes obvious when the angles C−Sn−Ca and O→Sn−halogen are compared. The Sn−halogen bonds are longer than in the precursor uncomplexed compounds.

An X-ray structure determination of cis-Me2SnHal2 · 2D (500) (D = N-methyl-pyrrolidin-2-one) shows that the coordination of the lactam ligand to Sn is realized via oxygen (Table 72). A comparative study of the bond lengths leads to the unexpected observation that the O→Sn bonds in 500a (Hal = Cl) are the longest in the series (2.446 and 2.460 Å). The O→Sn bond lengths are almost identical in 500b (Hal = Br), 2.323 and 2.345 Å, and in 500c (Hal = I), 2.294 and 2.326 Å. This effect might be even greater on going from Br to I, but the size of the ligand seems to become predominant.

The six-coordinate phosphine oxide complexes of diorganotins 501, 502a, 502b and 503 adopt the common cis-geometry at the Sn atom.

D₁ = 2-imidazolidino,
D₂ = N-methylpyrrolidin-2-one-O,
D₃ = catena-(μ²-meso-1,2-bis(n-propylsulfinyl)ethane),
D₄ = catena-(μ²-meso-1,2-bis(phenylsulfinyl)ethane),
D₅ = thirane-1-oxide-O,
D₆ = dimethylacetamide,
D₇ = 3H-imidazole-2-thione,
D₈ = 3H-imidazoline-2-thione.
The spectroscopic and X-ray studies of diphosphoryl adducts of diorganotin(IV) halides revealed that they possess different structures depending on the nature of organotin halide and the diphosphoryl ligand \(^{127,1056,1057}\). Thus, methylene-diphosphonates and -diphosphinates usually serve as bidentate chelating ligands, providing monomeric octahedral complexes preferably with the trans-R configuration for diorganotin adducts \(^{127,1056}\). Bridging by methylenediphosphoryl ligands appears to be rare \(^{1056,1057}\).

It has been established for methylenediphosphonate complexes that substitution of a halogen atom by a more electropositive organic group in the trans-position relative to phosphoryl leads to strengthening of the Sn–O bond together with a significant lowering of the \(^2J^{(119)Sn−31P}\) magnitude \(^{1057,1058}\). This influence also exists in ethylenediphosphonate adducts \(^{125}\).

**ii. Octahedral complexes with all-trans structure.** These diorganotin species are represented in Table 73 for N-donor ligands and in Table 74 for O-donor ligands, respectively. The tin atom exhibits slightly distorted octahedral coordination geometry with two X atoms, two methyl C atoms and the N atoms of two ligands in an all-trans configuration. The D → Sn, Sn–X and Sn–C bond distances are identical in the pairs. The bond angles around the six-coordinated tin do not deviate more than 2° from ideal.

The azole ligands are always bonded to the organotin(IV) moiety through their pyridine-like nitrogen atom (Table 73). In 1-methylimidazole (NMI) complexes of the type \(\text{R}_2\text{SnX}_2 \cdot \text{D}_2\) (504), the N → Sn bond distance in the iodide 504c \((\text{R}=\text{Et})\) \(^{356}\), 2.366 Å, is slightly longer than that in chloride 504b \((\text{R}=\text{Me})\) \(^{1060}\), 2.329 Å, and bromide 504c

| X = I |
| Et   | NMI (504c)   | 2.366      | 2.990    | 2.148    | 356       |

\(^{a}\)Im = imidazole, NMI = 1-methylimidazole, Pz = pyrazole, Ind = indazole, D¹ = 2-[(phenylethylimino)methyl] phenol-O.

(R = Me)\(^{356}\), 2.336 Å, in agreement with the lower Lewis acidity of diodo with respect to dichloro and dibromo diorganotin species.

The structures of indazole (Ind) complexes Me₂SnX₂ · 2Ind (505a (X=Cl) and 505b (X = Cl)) are very similar, with practically undistorted \textit{trans}-octahedral coordination\(^{1065}\). In spite of the different acceptor capacities of these two species, the N → Sn bond length in 505a is practically the same length as that in 505b, probably because of the hydrogen bond.

In the crystal phase, the molecule of the adduct is always stabilized by a complex network of intermolecular hydrogen bonds between the coordinated halide atoms and the N-H groups of the organic ligands of the neighboring units.

The bond angles around the six-coordinated tin in spirocyclic 506 and 507 do not deviate from the ideal \textit{all-trans} configuration\(^{1081,1082}\).

There is a comprehensive review of tin adducts with nitrogen heterocycles\(^{362}\).

For a long time all efforts at isolating both a five- and six-coordinated diorganotin dihalide adduct containing the same donor ligand had failed. The authors\(^{424}\) were successful in obtaining the precise conditions necessary to isolate 1 : 1 (Table 28) and 1 : 2
16. Hypervalent compounds of organic germanium, tin and lead derivatives

(Table 74) adducts of Ph₂SnCl₂ with Ph₃PO. The O → Sn bond length decreases from a value of 2.278 Å in the 1 : 1 adduct to a value of 2.214 Å in the 1 : 2 adduct (Table 74). The decrease in the O → Sn donor bond length was attributed to increased Snδ+–Clδ− character on formation of the 1 : 2 adduct. Despite this decrease, the P–O bond length remains unchanged and hence the ν(P=O) stretching frequency also remains essentially unchanged on addition of the second mole of Ph₃PO to Ph₂SnCl₂ (ν(P=O) = 1140 cm⁻¹) 424.

For dichloro 1092 and diiodo 356 diorganotin adducts, considerable evidence exists for Sn–halogen bond length differences between the cis and trans arrangements, the former having shorter distances.

c. X₃RM · D₂ systems. These complexes are generally more stable than those of R₂SnX₂ having the same ligand. In neutral octahedral 1 : 2 adducts RSnX₃ · 2D the monodentate

¹D¹ = quinoline N-oxide, D² = Ph₂P(O)CH₂CH₂P(O)Ph₂, D³ = 1,3-dimethylthiourea, D⁴ = 2(1H)-pyridinedithione-S.
²tetakis(purine) solvate.
³15-crown-5 solvate.
donor ligands D can be in a cis (508) or a trans (509) configuration. In the cis-isomer, the halide atoms can be arranged in two ways: fac- (at the corners of an octahedral face, 508a) and mer-arrangements (the tin atom is placed in the plane of the halide atoms, 508b).

Numerous compounds with a trans structure have been synthesized: EtSnCl\(_3\) · 2Ph\(_3\)PO\(^{1093}\), EtSnCl\(_3\) · 2(Me\(_2\)N)\(_3\)PO\(^{1094}\), EtSnCl\(_3\) · 2(Me\(_2\)N)\(_2\)CO\(^{1095}\), PhSnCl\(_3\) · 2(Me\(_2\)N)\(_3\)PO\(^{1095}\), EtSn\(_3\) · 2Ph\(_3\)PO\(^{1096}\) and EtSnBr\(_3\) · 2Ph\(_3\)PO\(^{1097}\), as well as the cis-fac compounds EtSn\(_3\) · 2(Me\(_2\)N)\(_3\)PO\(^{1098}\), n-BuSnCl\(_3\) · 2(Me\(_2\)N)\(_3\)PO\(^{1099}\) and the cis-mer compounds EtSn\(_3\) · 2Ph\(_3\)SO\(^{1100}\), n-BuSnBr\(_3\) · 2Ph\(_3\)SO\(^{1101}\).

In the octahedral Sn atom in BnSnCl\(_3\)(Phen) · C\(_6\)H\(_6\) (510) the two N atoms occupy positions trans to two of the Cl\(^1\) atoms, leaving one Cl\(^2\) atom trans to the C atom (Table 75)\(^{1102}\). As a result there are two classes of Sn–Cl interaction. The Cl atoms trans to the N atoms form longer Sn–Cl bonds (2.428 and 2.430 Å) than the Cl atom trans to the C atom (2.400 Å). However, in the crystal structure of the related n-butyl compound BnSnCl\(_3\)(Phen) (511)\(^{1103}\) one N-donor atom is trans to the organic substituent (cis-mer isomers), leading to disparate Sn–N bond distances\(^{1102}\).

\(i\)-PrSnCl\(_3\) · 2DMF (512)\(^{1104}\) and \(i\)-PrSnCl\(_3\) · 2DMSO (513)\(^{1105}\) are the only examples of 1 : 2 adducts of organotin trihalides with monodentate ligands containing oxygen as donor atoms which could be isolated as both fac and mer isomers. Both 512 and 513 showed a significant lengthening of the covalent Sn–Cl bonds in the hypervalent O → Sn–Cl fragments compared to bonds that lie cis to the O → Sn bond. In particular, for 513 the Sn–Cl bond lengths in the cis-fac isomers are 2.468 and 2.480 Å as compared with 2.398 Å (2.445, 2.463 and 2.410 Å, respectively, for another asymmetric unit) while in the cis-mer isomers the corresponding distance is 2.497 Å as compared with those of 2.440 and 2.468 Å (2.491, 2.455 and 2.470 Å, respectively, for the other asymmetric unit)\(^{1105}\).

The \(^{119}\)Sn NMR spectrum of the adduct PhSnCl\(_3\) · (EtO)\(_2\)POCH\(_2\)CH\(_2\)PO(OEt)\(_2\) at \(-90^\circ\)C consists of a triplet at \(-557\) ppm and a doublet of doublets at \(-551\) ppm with approximately 5 : 1 relative intensities. These resonances were attributed to isomers of the hexacoordinate complex\(^{301,1056}\). The first isomer has two equivalent phosphorus atoms in the tin coordination sphere and consists of cis-fac octahedra in accordance with the preferred cis-bridging behavior of the ethylene-diphosphonate ligand. The second isomer with nonequivalent phosphorus atoms consists of cis-mer octahedra\(^{125}\).

16. Hypervalent compounds of organic germanium, tin and lead derivatives

**d. $X_4M\cdot D_2$ systems.** Organotin tetrahalide adducts of this type, where $X = \text{Cl, Br and I}$, $D = \text{monodentate ligand involving oxygen}$, $\text{nitrogen}$, $\text{phosphorus}$, and, to a lesser extent, $\text{sulfur}$ and $\text{selenium}$ as coordinating atom, are known. Perhaps the major point of interest in these bis adducts is the cis/trans isomerism around the metal atom. A search of the Cambridge Crystallographic Database reveals about 40 examples divided almost fifty-fifty between cis and trans isomers.

Studies of the SnX$_4$–THF reaction system ($X = F, \text{Cl, Br, I}$) have established an adduct SnX$_4$(THF)$_2$ formation only for $X = \text{Cl and Br}$, but not for $X = F$ and I. The metal–ligand (THF) bond distances in the trans-O–Sn–O linkage reflect the relative acceptor order: SnCl$_4 >$ SnBr$_4$.

There are no literature reports of structurally characterized SnF$_4\cdot D_2$ systems, and only one of a cis-bidentate ligand, i.e. SnF$_4(2,2'$-bipyridyl)$^{990}$. Some reports described SnF$_4$(MeCN)$_2$ as trans-adduct based on infrared and Mössbauer spectroscopic data$^{1113}$. Table 76 and 77 provide prominent structurally characterized examples of cis- and trans-SnX$_4D_2$ systems.

Comparisons of Sn–Cl bond distances for similar systems show little variation (Tables 76 and 77). Table 76 and 77 provide prominent structurally characterized examples of cis- and trans-SnX$_4D_2$ systems.

</table>
2H2O1114, 2.37–2.40 Å, are a little longer compared with 2.364–2.391 Å in trans-SnCl4( H2O)2·15-crown-51118.

There are several examples where both arrangements have been crystallographically characterized, e.g. in cis-SnBr4·2Ph3PO1120 and trans-SnBr4·2Ph3PO969, and there is one example where the two isomers have been found in the same crystal domain, e.g. in SnBr4·2Me2SS1110 there are two cis-SnBr4·2Me2S molecules and one trans-SnBr4·2Me2S molecule located in the unit cell.

Arguments used to explain the isolation of one isomer over the other have typically been based upon the solid adducts, but this is unsatisfactory since many systems show the coexistence of both forms in the solid state. It has been shown that adducts can undergo isomerization in the solid state, e.g. SnX4D2 with X = Cl, D = DMF, DMA or DMSO and for X = Br, D = DMF or DMA were obtained from solution as the cis isomers, and converted to the trans form by heating1121.

Solvent effects have been shown to be important in the isolation of particular adducts; both cis and trans forms of SnCl4·2THF have been crystallized, the cis from dichloromethane and the trans from n-pentane. Therefore, trans isomers are preferred in weakly polar solvents while cis isomers are favored in more polar media1112.

The reaction between Ph2SnCl2 and thiosemicarbazide using acetone–ethanol as a solvent mixture resulted in the formation of bis(acetone thiosemicarbazone-S)dichlorodiphenyltin. In the monomeric hexacoordinate complex, each of the two monodentate ligands coordinate to the tin atom through the sulfur atom to form a distorted-octahedral geometry (the S→Sn bond length is 2.712 Å)1122.

Complexation of SnHal4 (Hal = Cl, Br) with monodentate tertiary phosphines (Ph3P, Ph2MeP, PhMe2P and Bu3P) has been studied by 119Sn and 31P NMR spectroscopies in CH2Cl2 solutions at various donor/acceptor (D/A) ratios and depend on the temperature (−90 °C and +3 °C). Selected NMR parameters for the complexes are given in Table 78.

Analysis of the SnBr4−Bu3P system shows that only AD2 complexes exist in solutions at −90 °C independent of the D/A ratio. The values of δ(119Sn) and (31P) for the products isolated at D/A <0.5 at room temperature evidently show that formation of AD complexes takes place before the oxidation of phosphines occurs (oxidation of tertiary phosphines with excess of SnHal4 leads to an alternative mechanism for the formation of R3PHal+SnHal5−)26. In the SnCl4−Me2PhP system, in which only weakly dissociated AD2 complex exists at room temperature independent of the D/A ratios, oxidation of the phosphate proceeds extremely slowly26.

\[ Δδ = δ(\text{complex}) − δ(\text{phosphine}). \]
3. Lead

The differences between lead and tin bond lengths in mixed-ligand complexes are not equal for all bonds. The replacement of tin by lead leads to the lengthening of $N \rightarrow M$, $O \rightarrow M$ and $M \rightarrow Cl$ bonds by 0.11–0.20 Å (Table 79)\textsuperscript{437}.

Contrary to $Ph_2PbCl_2 \cdot 2Im$\textsuperscript{1124} and to $Ph_2Pb(NCS)_2 \cdot 2HMPA$\textsuperscript{1089,1125} with an all-\textit{trans} arrangement of ligands around the lead atom, in $Ph_3PbCl_2 \cdot 2DMSO$ and $Ph_2PbCl_2 \cdot 2HMPA$, the donor molecules and chlorine atoms are placed \textit{cis} to each other, with \textit{trans}-positioned phenyl groups\textsuperscript{437}. However, the bond lengths in polyhedra with \textit{cis} and \textit{trans} coordination are markedly different.

The rehybridization of the valence orbitals in lead complexes is more effective, i.e. the concentration of s-electrons in the Pb–C bonds is larger and/or the gap between the s- and p-levels of the lead atom is larger in comparison with tin\textsuperscript{437}. The high oxidation capacity of Pb$^{4+}$ and the high stability of Pb$^{2+}$ favor the last assertion. The more effective rehybridization leads to decreased electron-withdrawing capacity of the Pb$^2_2$ and Pb$^+_3$ groups, i.e. to increase in the Pb–X bond ionicity in phenyl halides and pseudohalides and to a greater redistribution of electron density in the hypervalent fragments. In \textit{cis} complexes of Pb$\text{MC}_2 \cdot 2D$ the difference between lead and tin for coordinate bonds $\Delta(D \rightarrow M) = 0.20$ Å (DMSO) and 0.16 (Bipy) are more than for the covalent bonds $\Delta(Pb–Cl) = 0.12$ Å, whereas in \textit{all-trans} $Ph_2M(NCS)_2 \cdot 2$HMPPT the corresponding values $\Delta(O \rightarrow M) = 0.18$ Å and $\Delta(N \rightarrow M) = 0.16$ Å are fairly close (Table 79).

The relative weakening of $D \rightarrow Pb$ bonds is not accompanied by an increased tetrahedralization of the residual moiety (the C–Pb–C and C–Sn–C angles are almost equal) as found in similar cases, since a concentration of s-electrons in the Pb–C bonds occurs simultaneously\textsuperscript{437}.

B. Chelate Complexes

Hexacoordinate neutral complexes of group 14 elements with only one multidentate ligand are much less known than those with two multidentate ligands.

\textsuperscript{4}$^a$\textit{\Delta} is the difference between values for lead and tin.  
\textsuperscript{b}Im = imidazole.
1. One multidentate ligand

Complexes 514, 516 and 517a–f (for substituents, see Table 80) are representatives of compounds containing tridentate coordinating ligands. In the solid state, hexacoordination of the tin atom in 514 results from two ether O → Sn interactions with bond distances of 2.553 (O1) and 2.540 Å (O2). The trans angles, i.e. O2 → Sn–Cl1, O1 → Sn–Cl2 and C–Sn–C, of 171.6, 154.2 and 155.5°, respectively, indicate significant deviations from the ideal geometry. In solution, a dynamic equilibrium including intramolecular O → Sn interactions is observed. The concentration-independent 117Sn chemical shift of compound 514 at −73.6 ppm (CDCl3) is different from that of a reference compound without a Lewis donor, i.e. n-BuPhSnCl2 (+45 ppm), but is fairly typical for a hypervalent diorganotin dichloride. Its alkyl 1J(119Sn–13C) coupling constants of 629 Hz also reflect a stronger coordination at tin as compared to n-BuPhSnCl2 (503 Hz).

X-ray data for tridentate complexes 515–517 were reported (Table 80). In 517a–c, the Sn atom has a distorted octahedral coordination geometry, with the halo ligand and the thiosemicarbazone moiety in the equatorial plane and the methyl groups in the axial positions. The two chlorines in 517d–f occupy the apical positions, while the ligand and the organic group are in the equatorial plane.

Synthesis and some properties of six-coordinate organotin compounds 426a, 426b, 428a, 428b and 430, containing the monoanionic O,C,O-coordinating ligand \{4-\text{t}-\text{Bu}-2,6-[PO(OEt)2]2C6H2\}−, were discussed in Section VII.B.2. Structures and X-ray data are presented in Table 81. X-ray investigations reveal weak intramolecular O → Sn interactions for 426a (2.865–3.063 Å) and 426b (2.939–3.108 Å) but strong O → Sn coordination for 428a (2.203/2.278 Å) and 430 (2.221–2.225 Å) (Table 81).

*R2 = HNN=C(Me)Pyr-2.

The existence of two independent molecules in the crystal unit of 426a is also reflected by the observation of two equally intense 119Sn MAS NMR resonances at −181.7 and −227.7 ppm. The NMR spectra show (Table 81) that strong O–Sn contacts are present in halides 428a and 430, whereas weak intramolecular coordination is observed in 426a and 426b. Moreover, in comparison with tetracoordinate Ph3SnCH2SiMe3 (Δ119Sn = −88.6 ppm), the 119Sn NMR data of 425b [δ(119Sn) = −127.5, J(119Sn−31P) = 38 Hz] indicate a coordination number greater than four at the tin atom in both solution and the solid state.

Other representatives of compounds with tridentate O,C,O-chelating ligand are complexes 518769, 519772 and 520773. The structural data for 519 and 520 are given in Table 81.

Complexes 521865, 5221132 and 5231132 are examples of hexacoordinate diorganotin compounds bearing dianionic tridentate O,N,O-chelating ligands.

Of special interest are coordination compounds formed by the interaction of the metal with potentially tetratedentate ligands. Among them are complexes 5241133 and 5251134 with...
16. Hypervalent compounds of organic germanium, tin and lead derivatives

O,N,O,O- and C,N,N,C-chelating ligands, as well as complexes containing tetraanionic, 526\textsuperscript{1135} and diatomic, 527\textsuperscript{1136}, 528a–c\textsuperscript{241,243} and 529\textsuperscript{1137}, O,N,N,O-chelating ligands. Selected X-ray data for these compounds are presented in Tables 82 and 83.

We exemplify selected structural parameters for some tetradeionate porphyrins (530), phthalocyanines (531a) and porphyrazines (531b) (M = Ge, Sn) in Table 84 but detailed discussion is beyond the scope of this review.

A germanium complex with ethylenediaminetetraacetic acid (Hedta) 532 has a pentadentate edta ligand with one protonated acetate group which does not coordinate, forming a six-coordinate complex 1150.

2. Two multidentate ligands

a. Four-membered chelate rings. The most favored and stable chelate ring is the five-membered ring; four- and six-membered chelate rings are also obtained. Four-membered
chelate rings are particularly strained and seldom formed. A very weak intramolecular O → Sn interaction in o-anisylstannanes (o-An)2SnPh2 (290), (o-An)2SnBr2 (292a), (o-An)2SnI2 (292b) and related compounds239,686,690 was discussed in Section VII.A.2.a (cf. Table 50). Other potential representatives of hexacoordinate four-membered chelates are carboxylates R2M(O2CR1)2 (533), dithiocarbamates [R2M(S2CNR1)2] (534) and xanthates [R2M(S2COR1)2] (535) (M = Ge, Sn, Pb). Selected structural data for some carboxylates 533 (M = Sn, Pb), dithiocarbamates 534 (M = Sn) and xanthates 535 (M = Sn) are given in Tables 85 and 86.

Crystallographic studies of organotin and organolead carboxylates revealed that their structures are dependent on both the nature of the substituent bound to the tin atom and the type of carboxylate ligand. The C–Sn–C angles of 122.2–154.6° found in R2Sn(O2CR1)2 (Table 85) are close to the average value of the two extremes (90° for the cis-isomers and 180° for the trans-isomers). This coordination geometry is best described as skew-trapezoidal bipyramidal. The skew-trapezoidal bipyramid can be envisaged as a distortion of a regular trans octahedron and it is especially favored if the chelate bite angle is small1151.

A secondary interaction with the nonbonding sulfur atoms is observed for dithiocarbamates Me2Ge(S2CNMe2)2 522 (2.685 Å) and Ph2Ge(S2CNEt2)2 1174 (3.183 Å). For the xanthate Ph2Ge(S2COMe)2, the O–Ge–S bite angle of 57.8° is much smaller than the C–Ge–C angles of 111.1° to 117.5°. The decrease allows the oxygen atoms to take up a distance of 2.920 Å from germanium, which is less than the sum of the van der Waals radii. On a relative scale, the S → Ge secondary interactions for the dithiocarbamates are 20–40% longer than the sum of the covalent radii, whereas the O → Ge distance in the xanthate is approximately 50% longer.

Crystallographic studies revealed three distinct structural motifs for diorganotin dithiocarbamates R2Sn(S2CNR1)2 534 (Table 86)126. For the predominant motif, the geometry about the Sn atom is skew-trapezoidal bipyramidal with the basal plane defined by the four S atoms derived from two asymmetrically chelating dithiolate ligands, i.e. the shorter and longer Sn–S bond distances are approximately 2.5 and 3.0 Å, respectively. For the dithiocarbamates that adopt this motif, the Sn-bound substituents represented include R = Me, n-Bu and c-Hex. Similar geometry was found in the related xanthate derivatives R2Sn(S2COR1)2 (535, R = Me, Ph).

In the second motif, the chlorine substituents in 534, R = Cl are sufficiently electronegative to increase the Lewis acidity of the tin atom that is most favorable for hypervalent S → Sn–Hal interactions. The result is that coordinate interactions are arranged in a trans fashion with almost symmetric chelation by the dithiocarbamate ligands in a distorted octahedral geometry 535. The related compounds X2Sn(S2CNEt2)2, where X = Cl, Br and I1197,1198, also feature cis-octahedral structures. A similar structure is found for four monodentate ligands, i.e. in [Sn(S2CNEt2)4]1199. The different configurations are shown nearby.

When one chlorine of [Cl2Sn(S2CNEt2)2] is replaced by a vinyl1200 or phenyl243,1192, the cis-octahedral geometry remains. Moreover, a six-coordinate, distorted octahedral geometry is found in the structure of Ph2Sn(S2CNEt2)21188,1189. The phenyl groups occupy approximate cis positions, i.e. the C–Sn–C angle is approximately 102° compared with the C–Sn–C angles of 125–150° found in the predominant motif described above. Symmetrical Sn–S distances are also found for Ph2Sn(S2P(OPr-i)2)2 1196. This structure is situated about a crystallographic center of inversion, which constrains the C–Sn–C angle to 180°. In contrast, in vin2Sn(S2CNN2)2 (R12, c-Hex) with lower Lewis acidity, the geometry about the tin atom is best described as being distorted octahedral (a skew-trapezoidal bipyramidal), with a trans disposition of the vinyl groups126.

² cis, cis-octahedral; trans, skew-trapezoidal bipyramidal.
³ Polymorph.
⁴ Monoclinic polymorph.
⁵ Two different R¹ groups.

Lewis acidity of the tin atom in R₂Sn is reduced, e.g. by substituting chloride for phenyl, the degree of symmetry in the Sn−S distances increases and the R−Sn−R angle deviates from 90°.

It has been found that in the absence of crystal packing effects, the solid-state geometries converged uniformly to more symmetric structures. For the dithiocarbamate ligands in the more symmetric tetragonal form Ph₂Sn(S₂CNEt₂)₂, the average Sn−S bond distance is 2.608 Å¹¹⁹⁰ with slightly asymmetric Sn−S distances (Δ(Sn−S) = 0.103 Å). In contrast, in the monoclinic form the average Sn−S distance is 2.644 Å with Δ(Sn−S) = 0.219 Å¹¹⁸⁹.

In Table 88 are collected selected structural parameters for some hexacoordinate complexes with potential bidentate S,N-coordinating ligands of the type 536. According to X-ray data, the tin atom in these compounds has a highly distorted octahedral geometry with the two S atoms in cis-position and the two nitrogen and two carbon atoms at angles between 90° and 180° (CSnC about 130° and NSnN about 150°).

In the (2-chlorobenzyl)tris(pyridine-2-thiolato)tin, two of the three pyridine-2-thiolato ligands (SPyr) are bidentate and one is monodentate¹²⁰⁷. The axial bond angles N−Sn−C (157.9°), N−Sn−S (154.3°) and S−Sn−S (144.6°) demonstrate the heavy distortion of the octahedron. The N → Sn distances of two of the SPyr ligands (2.303 and 2.324 Å) are shorter than in p-TolSn(SPy)₃ (2.466 Å)¹²⁰⁸, MeSn(SPy)₃ (2.483 Å), PhSn(SPy)₃ (2.432 Å)¹²⁰⁹ and Ph₂Sn(SPy)₂ (2.667 Å)¹²¹⁰, also with a N → Sn coordination. In contrast to the former, in these complexes as well as in Ph₂SnCl(SPy)¹²¹⁰, the SPyr fragment acts as a bidentate ligand and thus the Sn atom achieves coordination numbers of 7, 6 and 5, respectively. However, in Sn(SPy)₄ · HSPyr, the Sn atom was found not to be eight-coordinate, as might have been expected, but only six-coordinate, with two SPyr ligands being bidentate and the other two monodentate¹²¹¹.

The tendency toward hexacoordination in diphosphanylmethanide cis-octahedral complexes 537–539 follows the sequence: Ge < Si < Sn, quite different from the usually accepted order: Si < Ge < Sn¹²¹². The authors attributed this discrepancy to the low polarity of the M−P bonds and, in particular, to the especially nonpolar nature of the
Ge–P bond. For hypervalent bonds, it is the first structurally characterized example of a series ranging from silicon to tin with an identical set of ligands and with a low sum of electronegativities.

Complexes 540–543 are representatives of compounds containing two four-membered bidentate N,N-, O,O- and S,S-coordinating ligands. Selected structural parameters for these compounds, which point to their distorted octahedral structures, are collected in Table 89.

b. Five-membered chelate rings (N → M). The reaction of (ClCH₂)₂GeCl₂ with N-TMS thiolactams in a 1 : 2 ratio proceeds under mild conditions (mixing at −196°C and room temperature allowed to be reached under a vacuum to remove the evolving Me₃SiCl) and leads to bis-chelates 544a–c (equation 85)¹²¹⁹. In the case of the caprolactam derivative a very small yield of the reaction product in a 1 : 1 ratio, i.e. thiolactim ether 156b, was isolated (Section VI.A.2).

According to X-ray structural data (Table 90), the Ge atom in thiolactim ethers 544a–c have a slightly distorted octahedral coordination by virtue of the two intramolecular N → Ge coordinated bonds with the all-trans arrangement around the central atom¹²¹⁹. The N → Ge distances (2.03–2.12 Å) are rather close and the Ge–Cl distances (2.40–2.42 Å) are somewhat shorter than those in (N–Ge) monochelate thioethers 156a and 156b (Section VI.A.2 and Table 36), but both distances are still essentially longer than in tetrahedral germanium compounds.

The tin atom in dichlorides [Me₂N(CH₂)₃]₂SnCl₂ (N → Sn distance of 2.403 Å¹²²⁰), (Me₂NCH₂CH₂CMé₂)₂SnCl₂ (2.448 Å¹²²⁰) and difluoride [Me₂N(CH₂)₃]₂SnF₂ · 2H₂O (545) (2.366 Å¹²²¹) shows slightly distorted all-trans octahedral configuration. The only
distortion from the ideal geometry can be attributed to some strain in the five-membered NSnC₃ ring. Below −50°C, ¹¹⁹Sn and ¹⁹F NMR coupling data indicate the existence of two isomers for 545, the major species having an all-trans structure as in the crystal state, while the minor species has a cis arrangement for the fluorine and for the nitrogen atoms and trans arrangement for the carbon atoms (equation 86). The ³J(¹¹⁹Sn−¹H) coupling through the Me₂N→Sn bond exists in both the slow- and fast-exchange ranges. Together with the loss of the ¹J(¹¹⁹Sn−¹⁹F) coupling at high temperature, this serves as evidence that the Me₂N→Sn coordination is maintained during the cis-trans isomerization which occurs through a dissociative mechanism involving tin–fluorine bond rupture₁²²¹.

Density functional B3LYP calculation performed on [H₂N(CH₂)₃]₂SnF₂ isomers of the model compound showed that the all-trans isomer is energetically preferred. However, the LUMO of the cis isomer is of lower energy than the LUMO of the former, which suggests that the fluoride attack at tin in solution leading to hexacoordinate anionic species (Section IX.B) can take place at the cis isomer⁹⁷¹b.

The cyclo-stannasiloxanes M(OSiPh₂)₂O, M = Sn[(CH₂)₃NMe₂]₂ (546)₁²²², Sn[(CH₂)₃N(Me)CH₂]₂ (547) and cyclo-M(OSiPh₂O)₂M, M = Sn[(CH₂)₃NMe₂]₂ (548)⁷₁⁶ exhibit reduced ring strain as a result of intramolecular coordination. The tin atoms adopt a distorted-octahedral configuration with the two carbon atoms and the two hypervalent N→Sn−O bonds in mutually trans configuration. The distortions from the ideal configuration are illustrated by the deviation from 180° of the trans angles C−Sn−C (546, 154.3°; 547, 167.4°; 548, 151.5°). The N→Sn distances increase from 2.621,

2.638 Å and 2.508, 2.518 Å for the six-membered $^{546}$ and $^{547}$ to 2.721, 2.811 Å for the eight-membered $^{548}$.

The intramolecular N → Sn distances in stannasiloxane $[\text{Me}_2\text{N}(\text{CH}_2)^2\text{CMe}_2]_2\text{Sn}(\text{OSiMe}_2)_2\text{O}$ ($^{549}$) of 2.879 and 2.957 Å$^{1222}$ are rather long. They are comparable with those found in $[(\text{CH}_2\text{N(Et)})\text{CH}_2\text{CH}_2\text{CH}_2]_2\text{SnS}_2$ (N → Sn 2.766 and 2.859 Å$^{1134}$) and $[(\text{Me}_2\text{NCH}_2\text{CH}_2\text{CH}_2)_2\text{SnS}]_2$ (N → Sn 2.810 and 3.158 Å$^{1223}$). It seems that the intramolecular N → Sn interactions in $^{549}$ prevent its polymerization in the solid state. For the related stannasiloxane $(t$-Bu)$_2\text{Sn}(\text{OSiPh}_2)_2\text{O}$, with no intramolecular donor function, a polymeric structure was observed in the solid state$^{1224}$.

The Sn atoms in organoelement oxides $^{550}$ exhibit distorted octahedral configurations with the carbon atoms in mutual trans and the oxygen and nitrogen atoms in cis positions$^{1225}$.

The diorganotin derivatives $^{551a-d}$, $^{552}$ and $^{553}$ reveal distorted-octahedral geometries for the tin atoms with cis donor (trans-R) configuration$^{1226}$. In contrast, the tin center in $^{554}$ exhibits a distorted-octahedral trans donor (cis-R) configuration, where the N → Sn distances of 2.362 and 2.377 Å are shorter than those in $^{551-553}$ (Table 91). These results
are in line with the observation made in Section X.A 2.a that octahedral cis- and trans-SnR₂ isomeric intermolecular adducts also exhibit rather different N→Sn distances (the cis arrangements having shorter distances).

Unlike 551a–d, for 552 no decoalescence of the N-Me resonances upon temperature lowering was observed and they remained equivalent on the NMR time scale of the measurement, indicating a very low activation barrier for enantiomerization. This indicates that the two N→Sn bonds are very weak. The different behavior observed for the diphenolate and dithiophenolate can be traced to the higher ionic character of the Sn–O versus the Sn–S bond, which makes the former kinetically more labile 1203. In contrast to the methoxy-substituted stannaindane 551a–d and 552, the chiral spiro-catecholate ($\sigma$-O₂C₆H₃OMe-3) 553 enabled observation of the two diastereomers as a 1 : 1 553-A and 553-B mixture 1226. The existence of the diastereomers is also reflected by the observation of two equally intense $^{119}$Sn CP-MAS resonances at $-193.0$ and $-199.8$ ppm. The
NMR spectral behavior of compounds 553 and 554 at low and room temperature means that, with kinetically more stable chelate catecholate ligands, the Sn−O bonds do not rupture. A mechanism which accounts for the coalescence of hexacoordinated stannaindane derivatives 553 and 554 (as well as the thiophenolate derivative 552) involves intramolecular N→Sn dissociation with a following enantiomerization by a Berry pseudorotation for pentacoordinated species\textsuperscript{1226} (equation 87).

In the crystal structure of triorganotin halide 555a, the two C(Ar) atoms are in trans position. For hypervalent bonds, the length of the N→Sn trans to the iodine atom is considerably longer (2.53 Å) than that trans to the methyl group (3.10 Å). The \textsuperscript{1}H, \textsuperscript{13}C
and $^{119}$Sn NMR spectra show that, at low temperature in solution, the compound exists in two geometrically different forms, one as found in the solid state and one with the all-cis configuration (555b). The assignment to isomers was based on the larger low-temperature $^2J(119\text{Sn}-1\text{H})$ and $^1J(119\text{Sn}-13\text{C})$ couplings for the two trans groups than for the third organic group in cis position. At higher temperatures a process involving interconversion between these two isomers becomes fast on the NMR time scale.

Both trans-C(Ar)-556a and all-cis-556b configurations exist as two crystallographically different molecules in crystalline (2-Me$_2$NCH$_2$C$_6$H$_4$)$_4$Sn with weak N $\rightarrow$ Sn interactions of both amino groups. The more symmetric isomer 556a has shorter coordinative bond lengths (3.16, 3.28 Å) than all-cis-556b (3.46, 3.68 Å).

The structure of diorganotin compounds with the general formula [R$_2$Sn(O$_2$CC$_5$H$_4$N-2)$_2$] (557, (a) R = Ph$^{1227}$, (b) R = t-Bu$^{1228}$ and (c) R = Me$^{1229}$ bearing five-membered N,O-coordinating ligand depends largely on the substituents. For monomeric structure 557a the phenyl groups are cis and the oxygen atoms are trans. In 557b the $t$-butyl groups are trans and one of the picolinate ligands chelate the tin atom via one oxygen atom and the nitrogen atom (the second oxygen does not coordinate to tin). For polymeric 557c the picolinate ligands chelate the tin atom via one oxygen atom and the nitrogen atom, but one picolinate coordinates intermolecularly to the tin atom leading to a polymeric structure making each tin atom seven-coordinate. The N $\rightarrow$ Sn distances of 2.393 and 2.507 Å in 557c are intermediate between those found in 557a for both N $\rightarrow$ Sn interactions (2.284 Å$^{1227}$) and 557b (>2.50 Å). The three different molecular geometries for compounds 557 may be explained in terms of electronic or steric factors associated with the Sn-bound R groups, but there are no consistent correlations between them and the structure found in the solid state.
Accumulated X-ray results on neutral (N → Sn) bis-chelate diorganotin structures indicate that the stereochemistry of the SnR₂ skeleton in the octahedral geometries is generally trans or distorted trans for dialkyltin complexes. The trans-SnR₂ geometries were exclusively obtained with monodentate ligands when X = halide or pseudohalide, but not so with bidentate ligands. If the cis–trans energy differences were small in these systems, it might be conceivable, by a suitable choice of the aryl substituents and/or the chelating ligand, to favor one geometrical isomer over the other and, perhaps, even to allow the isolation of both forms.

c. Five-membered chelate rings (O → M). The reaction of (ClCH₂)₂GeCl₂ with N-TMS lactams in a 1 : 2 ratio leads to relatively stable products of two types. Under kinetic control (an inert solvent, 80–100 °C), (N-Ge) bis-chelate 558a is not found when 558b and 558c are detected (equation 88, a), while under more drastic conditions, the reaction yields the thermodynamically more stable (O–Ge) bis-chelates 559a–c (equation 88, a,
The (N–Ge) bis-chelates 558b and 558c, isolated on a preparative scale, isomerize to the corresponding (O–Ge) bis-chelates 559b and 559c when boiled in p-xylene for 0.5–1.5 h (equation 88, b).

By this method, but using (BrCH2)2GeBr2, the (O → Ge) bis-chelates 560a–c were obtained under conditions of thermodynamic control1232. Furthermore, the acyclic amide dichloride [MeCON(Me)CH2]2GeCl2 (561) was prepared analogously1233.

The syntheses of mixed bis-chelates (Ln)2Ge(Cl)Y, where Ln is the bidentate n-membered lactamomethyl C,O-chelating ligand, obtained by replacing one chlorine atom in (Ln)2GeCl2 by a much better leaving group Y (Y = OTf, OClO3, BF4, I or I3), were described in Section VIII.A. In contrast, the replacement of both chlorine atoms of (Ln)2GeCl2 takes place if the nucleofugality of entering and leaving groups are nearly similar (Cl and Br, or Cl and F). Consequently, dibromide 560c was prepared by the reaction of dichloride 559c with both LiBr and Me3SiBr in a 1 : 2 ratio of reactants893. Analogously, difluorides 562a–c were synthesized by treatment of dichlorides 559a–c with an excess of AgF (equation 89)893.

The hexacoordinated state of the central atom in products 558–562 was established using IR spectroscopy and, in the case of (O–Ge) bis-chelates 559–562, also by X-ray
diffraction\textsuperscript{1231–1233}. The Ge atoms in these compounds have an octahedral coordination owing to the two intramolecular O→Ge coordinated bonds. However, unlike in thiolactim ethers \textsuperscript{554a–c}, both the chelate rings and the chlorine atoms have a \textit{cis}-orientation relative to each other.

The parameters of the Ge atom coordination in dichlorides 559\textsubscript{a–c}, 561, dibromides 560\textsubscript{a–c} and difluorides 562\textsubscript{a–c} (Table 92) are close to those in chlorides 142\textsubscript{b}, 1441\textsubscript{a–d} and bromide 149 containing the pentacoordinated Ge atom (Table 33). Nevertheless, the O–Ge and Ge–Hal bonds in the hexacoordinated dihalides under discussion are somewhat shorter than those in the corresponding monohalides. However, these distances are still significantly longer than those in tetracoordinated germanium compounds. Thus, these dihalides have two OGeHal hypervalent fragments. The use of six-coordinate germanium compounds with lactamomethyl C,O-chelating ligands as models of transition states in S\textsubscript{N} reactions involving the five-coordinate Ge atom was discussed\textsuperscript{478}.

The geometrical parameters of the valence environment about the Ge atom in dihalides 559–562 reflect pronounced regularities associated with the change in the size of the lactam ring and the replacement of the halogen ligands. On increasing the size of the lactam ring and on going from fluorides to chlorides and then to bromides, the coordination environment about the germanium atom approximates an octahedron, as is evident, for example, from the increase in the CGeC angles. The extent of the deviation of the geometry of two OGeX hypervalent fragments from the ideal octahedron is characterized by the deviation $\Delta \Omega$ (see above) from the ideal value ($2\pi$) corresponding to the symmetrical O–Ge–Hal hypervalent bond. For dihalides (L\textsuperscript{5})\textsubscript{2}GeX\textsubscript{2} with a five-membered lactam ring, compounds 559\textsubscript{a}, 560\textsubscript{a} and 562\textsubscript{a}, the $\Delta \Omega$ values for the fluoride, chloride and bromide are 52°, 43° and 38°, respectively.

Finally, the hypervalent bonds in structures with five-coordinate (a TBP environment) and six-coordinate (an Oh environment) atoms can be considered by taking into account the difference in the ranges in which the $\Delta \Omega$ values vary, viz $\pi$ and $2/3\pi$ for a TBP and an Oh, respectively\textsuperscript{478}.

Based on the $^1$H DNMR data\textsuperscript{1232}, it is suggested that both diastereomers with either a \textit{cis} or \textit{trans} arrangement of the Br atoms are present in solution of dibromides 560\textsubscript{a–b}. The polytopic rearrangement in dihalides (L\textsubscript{n})\textsubscript{2}GeX\textsubscript{2} is discussed below.

| TABLE 92. Selected structural parameters for neutral (O→Ge) bis-chelates (L\textsubscript{n})\textsubscript{2}GeX\textsubscript{2} |
|------------------|---|---|---|---|---|---|
| Compound | n | X | O→Ge (\textdegree) | X→Ge (\textdegree) | O–Ge–X (deg) | C–Ge–C (deg) | $\Delta \Omega$ (deg)$^a$ | Reference |

| 560\textsubscript{a} | 1 | Br | 2.203, 2.139 | 2.458, 2.472 | 172.1, 172.3 | 162.7 | 38 | 1232 |
| 560\textsubscript{b} | 2 | Br | 2.090, 2.111 | 2.520, 2.461 | 173.4, 173.1 | 163.8 | 30 | 1232 |
| 560\textsubscript{c} | 3 | Br | 2.089, 2.087 | 2.506, 2.483 | 174.1, 173.4 | 168.0 | 26 | 1232 |

$^a$ $\Delta \Omega = 2\pi - \Omega$, where $\Omega$ is the solid angle determined by the directions of four pseudo-equatorial bonds and containing an axial ligand ($\Delta \Omega = 0^\circ$ for ideal octahedron); the averaged values for two virtually identical hypervalent bonds in each molecule are given.

$^b$ The point drops out of the common series, likely because the unit cell of 559\textsubscript{b} contains a p-xylene molecule solvate.

$^c$ [MeC(O)N(Me)CH\textsubscript{2}]\textsubscript{2}GeCl\textsubscript{2}.
The general synthetic route to six-coordinate \((O-Sn)\) bis-chelates involves the reaction of a functionalized halide with metallic tin. In earlier papers the numerous examples of synthesis of estertins \(X_2Sn[CHCHR'COOR'']\)\(_2\) \((X = Br, I; R, R' = H, Me, CH_2COOR''; R'' = Alk)\)\(^{1234-1236}\), the amide derivatives \(X_2Sn[CHCHR'CONR''R''']\)\(_2\) \((X = Br, I; R, R' = H, Me, Et, Ar)\)\(^{1237,1238}\) and the ketone derivatives \(X_2Sn[CR_2CH_2COR']\)\(_2\) \((X = Cl, Br, I; R = H, Me; R' = Alk, Ph)\)\(^{1239}\) involved the use of the corresponding halo-esters, -amides and -ketones as precursors. The first hypervalent tin species containing a C,Y-chelating ligand, the dibromide \(Br_2Sn[CH(COOEt)CH_2COOEt]\) \((563)\), whose structure was established by X-ray analysis, has been prepared by the reaction of metallic tin with diethyl bromosuccinate\(^{1240,1241}\). On the other hand, the structure of the first representative of analogous ketone derivatives, diiodide \(564\), was established only recently\(^{1242}\).

The reaction of \(CH_2=CHCOOR\) with Sn/HX \((X = Cl, Br, I)\) can be considered as a convenient preparative variant of the direct method discussed above. A number of \((O-Sn)\) bis-chelate estertins \(X_2Sn[(CH_2)_2COOMe]\)\(_2\) \((338)\) were obtained by this way\(^{720,753}\), as well as by halide exchange reactions\(^{347}\) of dichloride \(338a\), including compounds \(338a-c\) characterized by X-ray crystallography (see Table 93 for structures). The mixed halide species, \(ClBrSn[(CH_2)CH_2COOMe]\)\(_2\) \((339)\)\(^{347}\), and the amide derivative, \(Cl_2Sn[CH_2CH_2CONH_2]\) \((565)\)\(^{722,907}\), were also described.

Syntheses of various hypervalent estertins produced from trichlorides \(329\) and \(335\) were discussed in Section VII.A.2.b. They include compounds whose structures were established by X-ray diffraction, in particular, dimeric hydroxide \(336\)\(^{182}\), sulfides \(351\) and \(352\)\(^{749}\), imine \(349\)\(^{741}\), as well as the DMTC derivatives \(337a\) and \(337b\)\(^{731,182}\).

Structures of hexacoordinate estertin compounds, i.e. species containing the ROOCCH_2-CH_2Sn moiety were partly discussed earlier (Section VII.A.2.b and Table 53). In the estertins \((R^1O_2CCH_2CHR^2)SnX_2\) \(338a-c\), ketone \(564\) and amide \(565\), the tin atom

\(^a\)Two independent molecules in the unit cell.
possesses a distorted octahedral geometry. The $\text{R}^1\text{O}_2\text{CCH}_2\text{CH}_2$ ligands are bidentate, with the carbonyl oxygen atoms $\text{trans}$ to the $\text{cis}$-halides or pseudohalides. Selected bond angles and lengths for estertins, ketone, amide, and the related compounds $303, 357, 566$ and $567$ are displayed in Table 93.

The $\text{cis}$ Sn–I bond lengths in the ketone $564^{1242}$ and ester $338b^{347}$ are 2.835–2.857 and 2.777–2.780 Å, respectively, longer, as expected, than the tin–iodide bond lengths in tetrahedral four-coordinate diorganotin diiodides (2.67–2.72 Å)$^{172,1247,1248}$.

The NMR spectra of $(\text{MeO}_2\text{CCH}_2\text{CH}_2)_2\text{SnX}_2$ show the following trends: (i) both $\delta^1\text{H}_\alpha$ and $\delta^{13}\text{C}_\alpha$ increase and (ii) both $2J(\text{Sn}–\text{H})$ and $1J(\text{Sn}–\text{C})$ decrease in the sequence $\text{X}_2 = (\text{NCS})_2, \text{Cl}_2, \text{ClBr}, \text{Br}_2, \text{I}_2$, which is the sequence of decreasing electronegativity of $\text{X}_2$ and decreasing mean Sn–X bond energies$^{347}$.

By applying the direct method, $(\text{O–Sn})$-bis-chelate dihalostannanes $(\text{L}^n)_2\text{SnX}_2$ $(568–570)$ were recently synthesized (equation 90)$^{1249,504}$. Analogously, the acyclic amide, dichloride $[\text{MeCON(Me)}\text{CH}_2]_2\text{SnCl}_2$ $(571)$, was obtained$^{1233}$.

The reactions of dichlorides $568a–c$ with lithium salts LiX ($X = \text{Br, I}$), unlike those of germanium derivatives (see equations 77 and 88), result in both cases in the replacement of the two monodentate ligands by nucleophiles to give dibromides $569a–c$ and diiodides $570a–c$ with retention of the configuration of the initial dichloride and with higher yields than in reaction $90^{504}$. The formation of a cation–anion complex $\{[(\text{L}^5)_2\text{Sn}($OH$)]^+\text{BF}_4^-\}_2$ by the reaction of $(\text{L}^5)_2\text{SnCl}_2$ with AgBF$_4$ is discussed in Section XI.B.

The reaction of the N-TMS caprolactam with $(\text{CICH}_2)_2\text{SnCl}_2$, unlike that of the germanium derivative (equation 88), proceeds under more drastic conditions and gives only a poor yield of dichloride $568c$ (18%), i.e. this synthetic route to six-coordinate (O–Sn) bis-chelates has no preparative importance$^{494}$.
The significant upfield chemical shifts of dihalides 568–570 in the $^{119}$Sn NMR spectra in CDCl$_3$ (about $-195$ to $-336$ ppm), and IR data in CHCl$_3$ are indicative of hexacoordination of the tin atom, i.e. of the presence of the two bidentate chelate ligands and two monodentate ligands.$^{504,1249}$

The conductivities of solutions of the tin dihalides under consideration are substantially lower than those of their Si analogues (only data for dichlorides are available), are slightly lower (in particular, as compared to dibromide $^{(560c)}$) than those of their germanium analogues (Table 64) and are close to the intrinsic conductivity of the CH$_2$Cl$_2$ solvent. This is indicative of an increased covalent character of the M–Hal bonds in dihalides $(L^n)_2$MX$_2$, (M = Si, Ge, or Sn) on going from silicon to germanium and then to tin compounds.

According to X-ray structural data, the configuration of the valence environment about the Sn atoms in dihalides $^{568a–c,1249,569a–c,570a,570b,504}$ and $^{571}$ (a cis arrangement of the Hal and O atoms) is identical to that discussed previously in six-coordinate germanium dihalides (Section X.B.2a) containing the MC$_2$O$_2$Hal$_2$ coordination unit (M = Ge or Sn) with an intramolecular O $\rightarrow$ M coordination and a six-coordinate M atom involved in two hypervalent O $\rightarrow$ M–Hal bonds. It is particularly remarkable that replacement of the O atom by the N atom (the MC$_2$N$_2$Hal$_2$ coordination unit) leads to a change of the configuration to transoid.$^{636,1221}$ Apparently, this is a manifestation of the difference in the donor properties of the O and N atoms.

A comparison of the parameters of the Sn atom coordination in the dihalides (Table 94) with the structures of analogous lactamomethyl halide derivatives of five- and six-coordinate Si and Ge derivatives (Tables 33, 34 and 90) demonstrates that the spatial array of the hypervalent fragments containing six-coordinate atoms is less sensitive to the replacement of the halide ligands and the central atoms.$^{504}$ The covalency of the M–Hal bond increases and that of the M–O bond decreases in the series M = Si, Ge and Sn.$^{494}$

When using the parameter $\Delta\Omega$ (see above) for comparison, it is evident that the replacement of a Ge by Sn leads to a decrease in the range over which the $\Delta\Omega$ value varies (from 12–15° to 8–10°) as the size of the lactam rings changes, as well as to some increase in the distortion from ideal octahedral coordination (on the average by 8°). The hypervalent units in dihalides 338a and 563 are more substantially distorted (Table 33) than those in dichlorides 568a–c, 565 and 571. It is reasonable to attribute the noticeable difference in the distortion of the octahedral coordination in 338a and 563 as compared with 565 to the higher donor ability of the O atom of the aminocarbonyl group than that in the alkoxycarbonyl group. The $\Delta\Omega$ value also decreases from 55° for the five-coordinate to 40° in the six-coordinate state in the case of monochloride $^{L^6}$SnMe$_2$Cl (361b)$^{494,758}$ and dichloride $(L^6)_2$SnCl$_2$ (568b).

\textsuperscript{a} \Delta\Omega = 2\pi – \Omega, where \Omega is the solid angle determined by the directions of four pseudo-equatorial bonds and containing an axial ligand (\Delta\Omega = 0° for ideal octahedron); the average values for two virtually identical hypervalent bonds in each molecule are given.

\textsuperscript{b} Two crystallographically independent molecules.

\textsuperscript{c} Average values over two hypervalent O\rightarrow Sn–Hal bonds are given.

Note that in the complex with monodentate ligands, Me\textsubscript{2}SnCl\textsubscript{2} \cdot 2DMF\textsuperscript{1039}, which has a similar environment about the Sn atom to that in dichlorides 568a–c and 571, the average lengths of the hypervalent O\rightarrow Sn and Sn–Cl bonds and the \Delta\Omega value (Table 94) are 2.39 Å, 2.47 Å and 31°, respectively, i.e. the O\rightarrow Sn bond is ca. 0.1 Å longer than the corresponding bonds in 568a–c and 571, indicating that chelation plays an important role in this case.

For each of the dihalides (L\textsuperscript{n})\textsubscript{2}MX\textsubscript{2} the methylene NCH\textsubscript{2}M protons displayed an AB spin system in the \textsuperscript{1}H NMR spectrum, but no splitting of the signals of the methylene \textsuperscript{13}C resonances occurs, indicating a nonequivalence of protons within each methylene group but no loss of its \textit{C\textsubscript{2}} symmetry on the NMR time scale. The free activation energies (\Delta\textit{G}\textsuperscript{#}) of the rearrangement of the hexacoordinated species 559–561 and 568–571 as well as [MeC(O)N(Me)CH\textsubscript{2}]\textsubscript{2}MCl\textsubscript{2} (M = Ge, Sn) found by dynamic \textsuperscript{1}H NMR spectroscopy are listed in Table 95. The values of the barriers for the polytopic rearrangement for Sn derivatives are normally 1–3 kcal mol\textsuperscript{−1} higher than those for their Ge analogues. An increase in the size of the lactam ring in the bidentate ligand is accompanied by an increase in \Delta\textit{G}\textsuperscript{#}. This change is more pronounced for the Ge derivatives. As in the above-considered halides of pentacoordinated silicon and germanium (Table 34), an increased nucleofugality of the substituent X in the series Cl, Br, I results in a decrease in the \Delta\textit{G}\textsuperscript{#} value. In the case of tin dihalides, this tendency is observed only for derivatives with five-membered lactam rings, i.e. for compounds with weaker O \rightarrow Sn coordinated bonds.

d. Six-membered chelate rings. Six-coordinate \textit{\beta}-diketonate diorganotin complexes with two identical symmetrical chelate ligands, such as acetylacentonate (572a and 572b\textsuperscript{501,1251}), generally adopt \textit{trans}-octahedral configuration\textsuperscript{1252}. In contrast, with asymmetric donors, in particular 4-acyl-5-pyrazolones (QH) and \textit{\beta}-diketonate complexes of the type 573 show X-ray crystal structures with strongly distorted octahedral geometry around tin, two different

(572a) $R = \text{Me}$
(572b) $R = \text{Bu}$
(574a) $R = \text{Me}, \ R^1 = \text{CCl}_3$
(574b) $R = \text{Bn}, \ R^1 = \text{OMe}$
(574c) $R = \text{Bu}, \ R^1 = \text{Ph}$
sets of Sn–O distances and a C–Sn–C angle of 180° (135–150°), which is best described as skew-trapezoidal bipyramidal (Table 96). Thus, increasing the octahedral distortion (decreasing C–Sn–C and O–Sn–O angles) is associated with a larger difference in the bond length between covalent and coordinate bonds. Closely related structures were found for 4-trichloroacetyl-5-pyrazolones 574a–c. However, they are significantly shifted toward trans-octahedral configuration (skewed trapezoidal bipyramidal) with the C–Sn–C angle of 154–164° (Table 96).

The dihalotin derivatives (Q)2SnX2 (X = F, Cl, Br and I) are probably cis octahedral in the solid state, whereas in solution they exist as a mixture of cis and trans isomers. It is not easily evident why a pseudo-C₃ symmetry exists (or why the trans configuration is not allowed). An apparent reason is the asymmetry of the ligand, since a symmetric β-acetylacetonate anion (acac) stabilizes the trans species (acac)₂Sn(CH₃)₂, which has the metal on an inversion center.

In 575 and 576 the tin atom is in a distorted octahedral environment coordinated by two trans-methyl groups and two bidentate ligands, which coordinate to the metal through the thiolato sulfur and the oxygen atoms. For 575, the Me–Sn–Me bond angle is 139.4° and the linear hypervalent fragment is deformed (161.2, 161.6°). The deviation from the regular geometry is probably due to steric hindrance produced by the trimethylsilyl groups. The corresponding values for 576 are 152.8° and 172.89, 173.90°.

Crystalline studies of neutral bis-chelate diorganotin complexes 577 indicate that the stereochemistry of 577a, 577b, 577c and dimethyl[bis(tetraphenyl-oxothioxodiphosphazane)]tin (574d) are ideal octahedral (X → Sn ← X = X–Sn–X = 180°).

In 575 and 576, the tin atom is in a distorted octahedral environment coordinated by two trans-methyl groups and two bidentate ligands, which coordinate to the metal through the thiolato sulfur and the oxygen atoms. For 575, the Me–Sn–Me bond angle is 139.4° and the linear hypervalent fragment is deformed (161.2, 161.6°). The deviation from the regular geometry is probably due to steric hindrance produced by the trimethylsilyl groups. The corresponding values for 576 are 152.8° and 172.89, 173.90°.

Crystalline studies of neutral bis-chelate diorganotin complexes 577 indicate that the stereochemistry of 577a, 577b, 577c and dimethyl[bis(tetraphenyl-oxothioxodiphosphazane)]tin (574d) are ideal octahedral (X → Sn ← X = X–Sn–X = 180°).
e. Miscellaneous. Complexes of other types were much less investigated. Complexes 578 and 579 are representatives of compounds containing two different bidentate chelating ligands. Selected X-ray data for 578 and 579 are given in Table 97.

XI. HEXACOORDINATE CATIONIC TIN COMPOUNDS

Hexacoordinate cationic organogermanium and organolead complexes, for which structures were established by X-ray crystallography, have not been reported so far.

A. Intermolecular Complexes

The ionic complex $580$ is the first crystallographic example of a species with a hexacoordinate organotin cation 291. The tin atom is bonded to a highly distorted octahedral arrangement of two $trans$-methyl groups (CSnC 158.5°), a chlorine atom and three nitrogen atoms with markedly different Sn−N bond lengths (2.291 (trans to Cl), 2.333 and 2.409 Å). The C−Sn distances of 2.054 and 2.096 Å are shorter than the standard values (2.14 Å)9, while the Sn−Cl bond length (2.65 Å) is one of the longest among hypervalent organotin chlorides. In the anion Me$_2$SnCl$_3^-$, the Sn atom is five-coordinate and has a TBP geometry with both equatorial methyl groups (Section IV, Table 13).

Complexes of the type [R$_2$Sn(D)$_4$]$^{2+}$(X$^-$)$_2$ containing an uncharged O-donor ligand D and noncoordinating anion X$^-$, for example with D = DMSO, Et$_2$SO, Ph$_3$PO, Ph$_3$AsO, HCONMe$_2$ and X$^-$ = Ph$_4$B, have been known for a long time 1271. More recently, a number of species with the same and other O-donor ligands including H$_2$O, DMSO, (H$_2$N)$_2$CO and other anions such as deprotonated dimesylamide and benzene-1,2-disulfonimide were reported 909,1271–1273.

An attempt to prepare dinuclear dication of the type [R$_2$Sn(D)$_2$(µ-OH)]$_2^{2+}$ by treatment of the dimeric hydroxide $581a$ with four equivalents of monodentate O-donor ligands resulted in the mononuclear ionic complexes $582a$, $582b$ 1274 and $582c$ 1272 (equation 91).

Some geometrical parameters for selected cases of cationic species of the type [R$_2$SnD$_4$]$^{2+}$ which were characterized by X-ray analysis are given in Table 98. In all cases, complexes containing a C$_2$O$_4$ moiety (entries 1−5) consist of $trans$-octahedral
centrosymmetric \([R_2SnD_4]^{2+}\) cations (583) with a linear \(C-Sn-C\) bond, near-ideal \(cis\)-angles and somewhat short \(Sn-O\) bonds at 2.18–2.24 \(\AA\), as compared with uncharged hexa- and pentacoordinate complexes, such as \(Me_2SnCl_2(PyO)_2\) (2.25 \(\AA\))\(^{958}\) and \(Me_2SnCl_2(LuO)_2\) (2.29 \(\AA\), LuO = lutidine-N-oxide)\(^1^{69}\), as well as with cationic pentacoordinate intermolecular complexes (2.23–2.33 \(\AA\), Section VIII.B.1). In particular, in cation \([Me_2Sn(H_2O)_4]^{2+}\) (entry 1), the \(CSnC\) angles are 178.9° and 180° for two independent cations, and the mean values of the \(Sn-O\) and \(Sn-C\) bond lengths are 2.229 and 2.088 \(\AA\), respectively\(^{1271}\).

\[
\begin{align*}
[Me_2Sn(A)(\mu-OH)]_2 & \xrightarrow{4 \text{ D}} [Me_2Sn(D)_4]^{2+} \cdot 2[(MeSO_2)_2N]^- \\
(581a) \ A^- = (MeSO_2)_2N^- & \quad (582a) \ D = PyO (pyridine-1-oxide) \\
(581b) \ A^- = \text{o-C}_6\text{H}_4(SO_2)_2N^- & \quad (582b) \ D = DMSO \\
& \quad (582c) \ D = (H_2N)_2C=O
\end{align*}
\]

(583) \(R = \text{Me, Ph}; D = \text{O-donor}\)

In the mixed-ligand complex \([Ph_2Sn(NO_3)(DMSO)_3]^{2+}(NO_3)^-\), the tin atom is hexa-coordinated due to the presence of isobidentate \(NO_3\) ligand\(^{1281}\).

A series of cationic diorganotin complexes 584a–c containing 1-methyl-2(3\(H\))-imidazolinethione (Hmimt) as S-donor ligand were recently synthesized and characterized by IR, Raman, Mössbauer as well as \(^1\)H, \(^{13}\)C and \(^{119}\)Sn NMR spectroscopy\(^{1277–1280}\). Crystallographic studies of 584a–c and 584c · \(H_2O\) (entries 12–15) showed that all four cations have a near-octahedral geometry. The tin atoms lie on a crystallographic center of symmetry and are coordinated to two carbon atoms and to the S atoms of the four Hmimt ligands. The nitrate ions are involved in hydrogen bonding with the NH groups of the ligands. The Hmimt ligand, bound via the S atom, maintains its thione form in the complexes.

bAverage value.

cTwo independent cations.

dC₅SnC.
eThe longer bond being trans to a Me group.

The ionic dichelates 585 and 586 were recently described. A solvated variety of 586, 586a · Et₂O · MeCN, was unexpectedly isolated by thermal degradation of 586 in MeCN/Et₂O solution. Crystallographic studies showed all three species (Table 98, entries 6–8) to have a moderately distorted octahedral C₂O₄ geometry similar to the related nonchelate complexes discussed above, with the tin atoms lying on crystallographic inversion centers and short Sn–O bonds of 2.18–2.23 Å.

As in equation 91, destructive complexation of the dimeric hydroxide 581b with two equivalents of 1,10-phenanthroline or Ph₃PO produced, along with Me₂SnO and H₂O, the ionic complex 587 and the neutral compound 588. X-ray analysis showed that the cation of 587 (entry 11) has a severely distorted cis-octahedral C₂N₄ coordination arrangement around tin and it represents an example of a dicaticonic dichelate [R₂Sn(L₂)₂]²⁺ in order to adopt a cis structure (C₅SnC 108.4°).

In the uncharged all-trans complex 588 (entry 9), which may be also considered as a zwitterionic species, the heteroligands are O-bonded in a monodentate fashion to Sn that resides on a crystallographic center of inversion [Sn–O(S) 2.274, Sn–O(P) 2.119 Å, cis-angles = 87–93°]. A similar zwitterionic structure was found for Me₂Sn(OPPh₃)₂[N(SO₂Me)₂] (entry 10), where the dimesylamide groups act as...
\[

\end{align*}
\]
monodentate O-ligands, and the tin atom features an all-trans octahedral geometry with Sn–C 2.093, Sn–O(S) 2.274, Sn–O(P) 2.211 Å, cis-angles of 87–93° and SnOP 165.4°.

**B. Intramolecular Complexes**

A family of ionic 1 : 1 or 2 : 1 or complexes was recently prepared by the reaction of RSnCl3 (R = Me, Ph or n-Bu) and SnX4 (X = Cl, Br, or I) with appropriate amounts of potentially tridentate tris(pyrazol-1-yl)methane ligands (Pz = pyrazole), as shown by equations 92a–d. The stoichiometries of the compounds obtained depend strongly on the number and position of the methyl groups on the azole ring of the neutral ligand.

\end{align*}
\]

Crystallographic studies of 589a, 590 and 591a showed that all three cations are very similar. The Sn atom has a strongly distorted octahedral environment with the Sn–N bonds in the range 2.22–2.33 Å (the bonds trans to the carbon atoms are slightly shorter than those trans to halides). The Sn–N, Sn–C (2.214 Å in 589a, 2.17 Å in 591a) and Sn–Cl (2.37–2.40 Å) distances are all markedly different from those found in the cation of 580, presumably owing to the lower Lewis acidity of the R2SnCl+ moiety with respect to that of the RSnCl2+ acceptor. The Sn–Br distances are in the range of 2.51–2.52 Å in the cation and 2.48–2.51 Å (equatorial) and about 2.56 Å (axial) in the anion of 590. In the anions, the Sn atoms are five-coordinate (TBP) in MeSnCl4− and SnBr5− and six-coordinate (octahedral) in n-BuSnCl52−.

Hexacoordinate cation [FMeSn(CH2CH2NHMe)2(CH2CH2NMe)N]+BF4− (449) containing tricyclic atrane framework was discussed in Section VII.C.1877.

A new cation–anionic complex of hypercoordinate tin (593) was obtained by treatment of (L5)2SnCl2 (L5 is a bidentate (2-oxopyrrolidino)methyl C,O-chelating ligand) with AgBF41250. As in the case of (L7)2GeCl2 (Section VIII.A), the reaction occurs with replacement of both Cl atoms. As shown by X-ray crystallography, the reaction product, however, has a dimeric distannoxane structure, in which both tin atoms are stannacenium.
ion moieties stabilized by intraionic $O \rightarrow Sn$ coordination bonds. The $BF_4^-$ anions are bound to the dications through $O-H \cdots F$ hydrogen bonds (the $H-F$ distance is 1.78 Å). The octahedral coordination of the Sn atoms is strongly distorted because of a weak additional interaction with the solvate molecules of dioxane (the Sn–O distance is 3.16 Å).
XII. ACKNOWLEDGMENTS

The authors wish to thank all their colleagues who have been involved in the chemistry of hypervalent compounds of germanium, tin and lead and whose names have been cited in the text. We are indebted to Sergei Pogozhikh for calculations of the deviation of the central metal atom from the equatorial plane and to Sergei Artamkin, Tatyana Baukova, Sergei Bylikin, Evgeniya Kramarova, Nikolai Troitski and Aleksei Shumsky for assistance with the preparation of the manuscript. We are also grateful to RFBR for the financial support for a licence to use CCDB (grant No. 99–07-90133).

II. INTRODUCTION

Although transition metal germanium\(^1\), tin\(^2\) and lead\(^3\) complexes have been known for a considerable period of time compared to the area of transition metal–silicon chemistry, studies on these systems are less developed. There are a variety of reviews, or
sections of larger reviews, concerning various aspects of Ge$^{4,5,b,c}$, Sn$^5$ and Pb$^{4b,c,5b,c,6}$ transition metal chemistry. It is the purpose of this review to concentrate upon the synthesis and reactivity of Ge−, Sn− and Pb−transition metal complexes. In the case of Sn, we have emphasized the more recent studies, post 1990, except in those topics not covered in the previous reviews. The review is organized in terms of the different synthetic approaches to the metal–E bond (E = Ge, Sn or Pb) followed by selected areas of reactivity for each group 14 element in sequence. We present a limited set of structural and spectroscopic data.

### III. ORGANOGERMANIUM TRANSITION METAL COMPLEXES

#### A. Synthesis of Transition Metal Germanium Single Bond

There is a range of synthetic techniques available for the preparation of such bonds and these are discussed sequentially. In Tables 1–4 we present representative examples of complexes containing metal germanium single bonds: monometallic complexes (Table 1), bimetallic complexes (Table 2), monometallic digermyl, germylsilyl and germylstannyl complexes (Table 3) and bridging germylene bimetallic complexes (Table 4). Similar examples of complexes containing metal–germanium double and triple bonds are presented in Tables 5 and 6, respectively, and selected structural parameters are recorded in Tables 7, 8 and 9. Tables 1–9 appear at the end of this section.

1. Synthesis from transition metal anions and germyl halides

The first transition metal germanium complexes were synthesized by this route from metal carbonylates and triphenylbromo germane and since then, a large number of germyl, oligogermyl/silyl and germole complexes with a range of metals, Cr$^7,8$, Mn$^{1,8–11}$, Fe$^{1,8,9,12–21}$, Co$^{8,9,19,22–25}$, Ni$^{26,27}$, Mo$^{7,8,28–30}$, Rh$^{31,32}$, W$^{7,12,17,28,30}$, Re$^{33–35}$ and Os$^{36,37}$, have been synthesized using this approach. The reactions are usually performed in THF or related ethereal solvents and the products are obtained in good yield. Representative reactions are shown in equations 1–3.

$$\begin{align*}
\text{THF} & \text{M}^{-} \text{Na}^{+} + \text{ClGeR}_3 & \overset{\text{THF}}{\rightarrow} & \text{M}^{\text{GeR}_3} + \text{NaCl} & \quad (1) \\
& (\text{M} = \text{Mo, W}) & & (R = \text{Me, Et, Pr, Ph}) \\
\text{THF} & \text{Re}^{-} \text{Li}^{+} + \text{Cl}_2\text{GePh}_2 & \overset{\text{THF}}{\rightarrow} & \text{Re}^{\text{GePh}_2\text{Cl}} + \text{LiCl} & \quad (2) \\
& & & (1,9) \\
\text{Ge} & \text{Br} + \text{Na} [\text{ML}_n] & \rightarrow & \text{ML}_n^+ & \quad (3)
\end{align*}$$

$\text{ML}_n = \text{Co(CO)}_4, \text{Mn(CO)}_5\text{Fp}$
Functional groups on germanium, including hydrides, can be introduced via the reactivity of the labile Ge−Cl bonds\textsuperscript{17,33}, vide infra.

2. Synthesis from transition metal halides and germyl anions

Germyl metallocene derivatives of the early transition metals, Ti, Zr and Hf (M) have been synthesized by the combination of metallocene halides and germyl anions (equations 4 and 5)\textsuperscript{38−40}. The cyclopentadienyl complexes Cp\textsubscript{2}M(GePh\textsubscript{3})Cl\textsuperscript{39} are difficult to purify due to their instability in solution; however, use of the pentamethylcyclopentadienyl group (Cp\textsuperscript{*}) enhances both the solubility and stability of these complexes\textsuperscript{40,41}.

\[
\text{Cp}_2M \text{Cl} + \text{LiGePh}_3 \rightarrow \text{Cp}_2M\text{GePh}_3 + \text{LiCl} \quad (M = \text{Ti, Zr, Hf})
\]

(4)

\[
\text{Cp}_2M \text{Cl} + \text{LiGe(SiMe}_3)_3 \rightarrow \text{Cp}_2M\text{Ge(SiMe}_3)_3 + \text{LiCl} \quad (M = \text{Zr, Hf})
\]

(5)

Group 10 and 11 transition metal germanium complexes are formed by the same general route (equations 6−8)\textsuperscript{42−48}. Treatment of cis-(Et\textsubscript{3}P)\textsubscript{2}PtCl\textsubscript{2} with one equivalent of bis(trimethylgermyl)mercury resulted in the replacement of one chlorine atom selectively with the inversion of configuration and resulted in the formation of a trans-(Et\textsubscript{3}P)\textsubscript{2}PtCl(GeMe\textsubscript{3}) complex\textsuperscript{44,45}.

\[
\text{trans-}(\text{Et}_3\text{P})_2\text{MCl}_2 + 2\text{LiGePh}_3 \rightarrow \text{trans-}(\text{Et}_3\text{P})_2\text{M}(\text{GePh}_3)_2 + \text{LiCl} \quad (M = \text{Pd, Pt})
\]

(6)

\[
\text{cis-}(\text{Et}_3\text{P})_2\text{PtCl}_2 + (\text{Me}_3\text{Ge})_2\text{Hg} \rightarrow \text{trans-}(\text{Et}_3\text{P})_2\text{Pt}(\text{GeMe}_3)_2\text{Cl} + \text{HgCl}_2 \quad (M = \text{Pd, Pt})
\]

(7)

3. Anionic germyl metal carbonyl complexes

The anionic complexes of Cr, Mo and W were synthesized by the photochemical displacement of CO from M(CO\textsubscript{6}) by the [GeCl\textsubscript{3}]\textsuperscript{−} anion. The resulting anions were stabilized as tetraphenylarsonium salts, [Ph\textsubscript{4}As]\textsuperscript{+}[M(CO\textsubscript{5}GeCl\textsubscript{3})]\textsuperscript{−}\textsuperscript{49,50} and were also prepared by a reaction of Ph\textsubscript{3}GeLi with [M(CO\textsubscript{5}Cl)]\textsuperscript{−}\textsuperscript{51,52}. Anionic diastereomers of Mo and W were obtained from a similar reaction of an optically active germyl lithium MePh(1-naphthyl)GeLi with [(η\textsuperscript{5}-C\textsubscript{5}H\textsubscript{5})M(CO\textsubscript{2}NO)] (M = Mo, W) by the displacement of CO\textsuperscript{53}.

Phosphonium salts of anionic trihydridogermyl metal carbonyl complexes for V, Nb, Cr, Mo, W, Mn, Re, Co and Ni have been synthesized by substitution of carbonyl group with trihydrido germane, −GeH\textsubscript{3}\textsuperscript{54−56} (equation 9). Hydridogermyl metal complexes are the precursors for metal germynes and polynuclear metal germyl complexes\textsuperscript{57,58}.

\[
\text{CpM(CO)}_n + \text{K}^+[\text{GeH}_3]^- \xrightarrow{\text{Ph}_3\text{P}^+\text{Br}^-} [\text{Ph}_4\text{P}]^+[\text{CpM(CO)}_{n-1}\text{GeH}_3]^- \quad (9)
\]

4. Oxidative addition of germyl compounds to metal centers: germyl hydrides, Ge−H

Germyl hydrides readily undergo oxidative addition to the low-valent coordinatively unsaturated transition-metal complexes. Optically active [Co(CO\textsubscript{4})GeMe(1−Np)Ph] was
synthesized with retention of configuration at the asymmetric center from cobalt carbonyl and optically active germane\textsuperscript{59,60}. Germanium derivatives of Mn, Co, Fe, Ru, Os and Pt have been synthesized as illustrated in equation \textsuperscript{10}\textsuperscript{59–72}.

\[
\text{M}_2(\text{CO})_{2n} + 2\text{R}_3\text{Ge} - \text{H} \longrightarrow 2\text{R}_3\text{GeM}(\text{CO})_n + \text{H}_2 \quad (10)
\]

\[\text{M} = \text{Mn}(n = 5), \text{Co}(n = 4); \text{R} = \text{Me}, \text{Ph}, \text{CF}_3\]

The photochemical reaction of bis(hydridodimethylgermyl)methane/ethane, HMe\textsubscript{2}Ge(CH\textsubscript{2})\textsubscript{n}GeMe\textsubscript{2}H (n = 1, 2) with metal carbonyls of Fe, Co and Ru in pentane yielded a series of cyclic derivatives \textsuperscript{1} and \textsuperscript{2}\textsuperscript{73–79}.

\[
\begin{align*}
\text{(CH}_2)_n & \quad \text{Me}_2\text{Ge} \\
\text{M(CO)}_4 & \quad \text{GeMe}_2 \\
\text{(M = Fe, Ru)} \\
\text{(1)}
\end{align*}
\]

\[
\begin{align*}
\text{(CH}_2)_n & \quad \text{Me}_2\text{Ge} \\
\text{GeMe}_2 & \quad \text{(CO)}_3\text{Co} \\
\text{Co(CO)}_3 & \quad \text{CO} \\
\text{(2)}
\end{align*}
\]

Hydrogermoles, like the corresponding hydrosiloles, coordinate oxidatively to the metal centers in the \(\eta^1\) mode via the group 14 element and these complexes can act as catalysts for hydrogermylation reactions. An interesting reaction has been described between dicobaltoctacarbonyl and hydrogermole to afford \textsuperscript{3}, in which the germacyclopentenyl is coordinated to two cobalt carbonyl fragments in \(\eta^1\) mode as well as in rare allylic \(\eta^3\) mode (equation \textsuperscript{11})\textsuperscript{80}. Oxidative addition compounds \textsuperscript{4} and \textsuperscript{5} were obtained from the photolysis of M(CO\textsubscript{2})(PPh\textsubscript{3})\textsubscript{2} (M = Ru, Os) with tris(p-toly兴germane) in benzene in good yield (equation \textsuperscript{12}). The geometry around Os in \textsuperscript{5} is highly distorted and two carbonyl groups are \textit{trans} to each other\textsuperscript{61}.

\[
\begin{align*}
\text{Co}_2(\text{CO})_8 & + \\
\text{CH}_2=\text{CHCHCH}_2-\text{CH}=\text{CHMe} & \quad \rightarrow \text{Co}(\text{CO})_4 \quad \text{Ge} \quad \text{Ph} \\
\text{H} & \quad \text{Co}(\text{CO})_3 \\
\text{(3)}
\end{align*}
\]

\[
\begin{align*}
\text{M(CO)}_2(\text{PPh}_3)_2 + \text{H-Ge(Tol-p)}_3 & \quad \rightarrow \\
\text{Ph}_3\text{P} & \quad \text{M} \quad \text{Ge(Tol-p)}_3 \\
\text{CO} & \quad \text{Ph}_3\text{P} \\
\text{(4) M = Ru} \\
\text{(5) M = Os}
\end{align*}
\]

Fluxional trihydridogermyl complexes of osmium OsH\textsubscript{3}(GeR\textsubscript{3})(CO)(P(Pr-i))\textsubscript{3} have been synthesized by the addition of R\textsubscript{3}GeH to the dihydrido-olefin Os complex OsH\textsubscript{2}(\(\eta^2\)-C\textsubscript{5}H\textsubscript{5})CH\textsubscript{2}=(CH=CH\text{Et})(CO)(P(Pr-i))\textsubscript{3} with the elimination of olefin\textsuperscript{67}. The oxidative addition of R\textsubscript{3}GeH to (\(\eta^5\)-C\textsubscript{5}H\textsubscript{5})OsCl(P(Pr-i))\textsubscript{3} affords a series of Os(IV) derivatives (\(\eta^5\)-C\textsubscript{5}H\textsubscript{5})OsH(GeR\textsubscript{3})(P(Pr-i))\textsubscript{3} with the displacement of one phosphine ligand\textsuperscript{68}. 
The thermal reaction of trans-(PhMe₂P)₂PtHCl with triphenyl germane afforded the trans complex 6 which, on reaction with 2 equivalents of MeLi followed by methanolysis, afforded selectively only the cis-Pt complex 7 (equation 13). The reaction is believed to occur through a platinate intermediate, Li⁺[PtMe₂(GePh₃)(PMe₂Ph)]−, that was characterized spectroscopically.63

\[
\text{trans-(PhMe₂P)₂PtHCl + HGePh₃ } \rightarrow \text{cis-Pt complex 7 (equation 13)}
\]

5. Oxidative addition of germyl-germanes, -silanes and -halides

The oxidative addition of the Ge–Cl bond was reported in square-planar \(d^8\) Pt(II) complexes [PtMe₂(N–N)](N–N = bipyridine, phenanthroline). The additions afforded a series of compounds [PtMe₂Cl(Ge₃Cl₃−n)(N–N)](R = Me, Ph, n = 1, 2, 3)\(^8\). Stereoselective addition of Me₂GeCl₂ to Pt(Pé₃)₃ resulted in the formation of \(\text{trans-(ClMe₂Ge)PtCl(Pé₃)}\)\(^2\). Similarly, 1,2-dichlorotetramethyldigermane, ClMe₂Ge–GeMe₂Cl, adds oxidatively to Pt(PR₃)₃(\(R = \text{Et, Ph}\)) in benzene at room temperature to produce high yields of isomeric mixture of (ClMe₂Ge)₂Pt(PR₃)₂, without the cleavage of Ge–Cl and Ge–C bonds (equation 14)\(^8\).83

\[
\text{Pt(Pé₃)₃ + ClMe₂Ge–GeMe₂Cl } \rightarrow \text{cis/trans-(ClMe₂Ge)₂Pt(Pé₃)₂ (equation 14)}
\]

The addition of the Ge–Ge bond in a strained digermacyclopropane to Pd(PPh₃)₄ is also reported\(^8\). The Si–Ge bonds of 2,2-bis(organosilylgermyl)dithiane 8 undergo facile addition across the Pd⁰ and Pt⁰ complexes.85 The reaction of dithiane 8 with PdL₂ produced a four-membered square-planar bis(germyl) Pd complex 9 with the elimination of disilane, whereas an analogous reaction of dithiane 8 with a platinum–isonitrile complex resulted in the formation of a mixture of octahedral bis(germyl)bis(silyl) platinum 10 along with a tetrakis(germyl) Pt(IV) complex 11 in a low yield (equation 15).
A variety of metal carbonyls, $ML(CO)_n$, $M = Fe, Co, Mo$ and their derivatives undergo oxidative addition of Ge–Cl bonds subsequent to CO elimination (equation 16)\(^{22,86-93}\).

$$LM(CO)_n + GeX_4 \rightarrow (CO)_{n-1}LMGeX_3 + CO$$

(16)

M = Fe, $n = 5$; M = Co, L = Cp, $n = 2$;
M = Mo or W, L = bipy; $n = 4$

Reaction at a higher temperature leads to the formation of bis(germyl)metal carbonyls that exist as a mixture of two isomers (equation 17)\(^{87,88}\). The latter complexes were also synthesized directly by an exchange reaction between Na$_2$Fe(CO)$_4$ and R$_3$GeCl\(^{19}\).

$$2(CO)_4FeGeX_3 + high temp GeX_3(CO)_4FeGeX_3 + FeX_2 + 4 CO$$

(17)

Treatment of Mo(II)\(^{94-96}\), W(II)\(^{94-96}\) and Au(I)\(^{97,98}\) complexes with one equivalent of GeCl$_2$·dioxane, in CH$_2$Cl$_2$ at $-78\,^\circ C$ and subsequent warming to room temperature, resulted in rapid and clean insertion of germynes into the metal–hydrogen or metal–chlorine bond\(^{94-98}\). This is a convenient route to synthesize functionalized transition-metal germanium compounds\(^{99,100}\). The reaction is exemplified in equations 18 and 19.

$$GeCl_2\cdot dioxane + (Ph_3P)AuCl \rightarrow (Ph_3P)AuGeCl_3$$

(18)

$$GeCl_2\cdot dioxane + MOC CO CO RMOC CO CO GeCl_2R$$

(19)

Insertion of highly reactive group 14 carbene analogs into metal–metal bonds is a step toward cluster building and germynes readily insert into the Fe–Fe bond of [CpFe(CO)$_2$]$_2$ under mild conditions (equation 20)\(^{101}\).

7. Elimination reactions using germyl hydrides

Germyl copper compounds, obtained in a very low yield by the salt-elimination method\(^{42}\), can be obtained efficiently from the reaction of germyl hydrides with alkoxy...
copper compounds. The reaction involves elimination of the appropriate alcohol and is performed in DME in the presence of a phosphine (equation 21). Similarly, elimination of methane drives the reaction of Ph₃GeH with dimethyltitanocene resulting in the quantitative formation of 12 (equation 22).

\[ t\text{-BuOCu} + R_3GeH + 2 \text{PPh}_3 \rightarrow R_3GeCu(\text{PPh}_3)_2 + t\text{-BuOH} \]  
(21)

\[ \text{CH}_3\text{TiCH}_3\text{GePh}_3\text{TiCH}_3 \rightarrow \text{Ph}_3\text{GeH} + \text{CH}_4 \]  
(22)

The V–Ge bond has also been synthesized by an analogous reaction.

8. Miscellaneous reactions

Mixed germyl/silyl tungsten complexes Cp₂W(GeR₃)(SiMe₃) have been synthesized by the addition of germanes R₃GeH (R₃Ge = GeMe₃, GeMe₂H, Ge(t-Bu)₂H, GePh₂H) to the tungsten silene complex Cp₂W(η²-SiMe₂=CH₂) (equation 23).

\[ \text{Cp}_2\text{W}_2\text{GeR}_2\text{SiMe}_3 \rightarrow \text{Cp}_2\text{W}_2\text{GeMe}_2\text{Ph} \]  
(25)

Two unusual and complex reactions leading to the formation of a metal germanium bond involve the photochemical treatment of germylsilyl and germylsilylmethyl complexes (equations 24, 25 and 25a).
The reaction illustrated in equation 24 involves a series of 1,3-alkyl, silyl and germyl migrations between the metal–silylene and germylene transients formed subsequent to an \( \alpha \)-elimination reaction initiated by the elimination of CO\textsuperscript{109}.

Metal–germene transients are involved after a \( \beta \)-elimination in the chemistry shown in equation 25. The chemistry of equation 25a is a rare example of the direct \( \beta \)-elimination of a silene to result in the germanium–metal bond formation\textsuperscript{108}.

Another example of an unprecedented synthesis of the Fe–Ge bond involves the thermolysis of the complexes (Me\(_2\)GeGeMe\(_2\))\([\eta^5\text{-C}_5\text{R}_4]\)Fe(CO))\(_2\)(\(\mu\)-CO)\(_2\)(R = H, Me) in xylene leading to the high yield formation of the rearranged cyclic complexes containing Fe–Ge bonds, [Me\(_2\)Ge(\(\eta^5\text{-C}_5\text{R}_4\))Fe(CO)]\(_2\)\textsuperscript{110}.

9. Digermene complexes

The platinum \( \eta^2 \)-digermene complex (Ph\(_3\)P)\(_2\)Pt(\( \eta^2 \)-GeMe\(_2\)GeMe\(_2\)) was obtained by the elimination of ethylene and H\(_2\) from the oxidative addition of tetramethyldigermane HMe\(_2\)GeGeMe\(_2\)H to (Ph\(_3\)P)\(_2\)Pt C\(_2\)H\(_4\) (equation 26)\textsuperscript{111}.

\[
\text{L}_2\text{Pt(C}_2\text{H}_4) + \text{HMe}_2\text{GeGeMe}_2\text{H} \rightarrow \text{L}_2\text{Pt}\left(\begin{array}{c}
\text{GeMe}_2 \\
\text{GeMe}_2
\end{array}\right) + \text{C}_2\text{H}_4 + \text{H}_2
\]

\( (L = \text{PPh}_3, \text{dppe}) \) \hspace{1cm} (26)

B. Synthesis of Bimetallic Bridging Germylene Complexes, LMGeR\(_2\)ML

Data on these compounds are collected in Tables 2, 4 and 8.

1. Complexes with a metal metal bond

The reactions of di- and trihydridogermanes with a range of metal complexes is an attractive route to bimetallic bridging germylene complexes. The triply-bridged germylene iron complex \textbf{13}, containing a metal metal bond, was obtained from the reaction of Me\(_2\)GeH\(_2\) with Fe\(_2\)(CO)\(_9\)\textsuperscript{69,91}, whereas an analogous reaction of Ph\(_2\)GeH\(_2\) with Fe\(_2\)(CO)\(_9\) yielded a yellow crystalline bis(\(\mu\)-germylene)(\(\mu\)-carbonyl) iron complex \textbf{14} (equation 27)\textsuperscript{19,112}.
Similarly, the reaction of Co$_2$(CO)$_8$ with diphenylgermane, Ph$_2$GeH$_2$, gave [Co(CO)$_3$]$_2$(µ-GePh$_2$)(µ-CO) in good yield$^{66}$; no bis(µ-germylene) Co complex was obtained. The use of phenyltrihydridogermane produces $^{15,113}$, and the methylgermane analog $^{16}$ undergoes reversible decarbonylation to the closed cluster Co$_3$(µ$_3$-GeMe)(CO)$_9$ $^{17}$ (equation 28)$^{23,114,115}$. This cluster undergoes addition or substitution reactions with phosphines/arines or metal carbonyls (Mo, W) to produce mixed metal clusters.$^{115}$ A wide variety of such cluster compounds has been reported from the reactions of cobalt carbonyls and monogermanes GeH$_4$, Me$_2$GeH$_2$ and MeGeH$_3$ or digermanes, Ge$_2$H$_6$ or Me$_3$GeGeH$_3$ in different stoichiometry involving extensive rupture of Ge−H, Ge−Ge and Ge−C bonds$^{116–121}$.

![Diagram](image-url)

An interesting series of bridging germylene complexes of Ru and Os, $^{18}$ and $^{19}$, were obtained from the thermolysis of Me$_3$GeH and M$_3$(CO)$_{12}$ (M = Ru, Os) involving cleavage of Ge−C bonds, along with bis-germyl complexes $^{20}$ and $^{21}$ (equation 29). Thermolysis of $^{20}$ or $^{21}$ yielded a mixture of trinuclear metal clusters $^{22}$ and $^{23}$ together with low yields of the binuclear $^{24}$ and $^{25}$ (equation 30)$^{64}$. Low yields of $^{23}$ and $^{25}$ were also obtained from the thermolysis or photolysis of a binuclear bis(µ-germylene) osmium carbonyl complex [OC$_4$Os(GeMe$_2$)]$_2$ in hexane at 100°C and were structurally characterized$^{36}$. The structure of $^{25}$ is similar to that of the iron analog$^{69,91}$. Related trinuclear clusters of Pd and Pt, [M(µ$_3$-Ge(NBu-t)$_2$(CO))$_3$ (M = Pd or Pt)$^{122}$, containing bridging amidogermylenes were obtained from the reaction of metal germynes [M(Ge(NBu-t)$_2$)$_3$] with CO$^{123}$.

![Diagram](image-url)
The photolysis of FpSiMe$_3$ or Fp*SiMe$_3$ in the presence of di- or trihydridogermanes is another attractive route for the synthesis of germylene bridged binuclear iron complexes. The reaction proceeds via initial loss of CO followed by oxidative addition of the germane and results in the formation of the (µ-germylene)(µ-carbonyl) diiron complex 26 and bis(µ-germylene) diiron complex 27 (equation 31)\textsuperscript{124–127}. These bridged complexes exist as the mixture of geometrical isomers in solution which can undergo either thermal or photochemical interconversion. Complexes 28 and 29 were obtained from the photolysis of Fp*SiMe$_3$ in the presence of trihydrido germanes, RGeH$_3$ (R = t-Bu, p-Tol). These diiron Fe⋯H⋯Ge 3-center 2-electron complexes are rare\textsuperscript{128}. Presumably, they are intermediates in the formation of bis(µ-germylene) diiron complexes 27 via H$_2$ expulsion\textsuperscript{124,126}.

\begin{equation}
\text{R}_5\text{FeSiMe}_3\text{OCOCGeFe} + \text{R'RGeH}_2 \xrightarrow{hv} \text{R}_5\text{FeSiMe}_3\text{OCOCGeFe}_{\pm} + \text{R}_5\text{FeSiMe}_3\text{OCOCGeFe}_{\mp}
\end{equation}

\begin{align*}
(26) & \text{R = t-Bu, R' = H} \\
(27) & \text{R = R' = p-Tol} \\
(28) & \text{R = t-Bu} \\
(29) & \text{R = p-Tol}
\end{align*}

2. Complexes without a metal metal bond

Bis(µ-germyl)iron carbonyl complexes without a metal–metal bond were synthesized by the reaction of Fe(CO)$_5$ with germanium tetrahalides and later by an alternate route involving high temperature reaction of Fe(CO)$_5$ with a bis(halogermyl)iron carbonyl complex. Ferrous chloride is a byproduct of these reactions (equation 32)\textsuperscript{86–89}.

\begin{equation}
4 \text{Fe(CO)}_5 + \text{2GeX}_4 \rightarrow \text{(CO)}_4\text{FeGeX}_3 + \text{2Fe(CO)}_5
\end{equation}
Hydrido(methyl)germyl iron complexes undergo elimination of methylgermanes to form four-membered cyclic $\text{Fe}_2\text{Ge}_2$ systems (equation 33)\textsuperscript{129–131}. The tendency for such condensation is directly related to the number of methyl groups on the germanium. The binuclear diiron complex undergoes intramolecular elimination of methylgermane to form a four-membered heterocycle illustrating that the cleavage of Ge—C and Ge—H bonds occurs under mild conditions.

\[
\begin{align*}
\text{(OC)}_4\text{Fe} & \quad \text{GeR}_2\text{H} \\
& \quad \text{GeR}_2\text{H} \\
& \quad -\text{GeR}_2\text{H}_2 \\
\end{align*}
\]

C. Synthesis of Transition Metal Germanium Double Bond Germylene Complexes

Data on these compounds are collected in Table 5.

The early development of transition-metal germylene chemistry is summarized in earlier reviews\textsuperscript{4b–d}. Therefore we summarize the transition-metal germylene chemistry developed after 1990. Such complexes can be divided into seven different types (I–VII) depending upon the nature of bonding between the metal and germanium atom:

1. Base-free metal germylene complexes

The reaction of kinetically stabilized germylenes with metal complexes has proven a useful and not surprising route to complexes containing a metal–germanium double bond. Thus, the reaction of germylenes containing bulky aryl groups with the metal carbonyls
of Fe, Cr and W in THF at room temperature provided the first examples of base-free germyleane complexes of these metals (equation 34)\textsuperscript{132–134}.

\[
\begin{align*}
\text{Ar} & \quad \text{Ge} ; \\
\text{M(CO)}_5/\text{THF} & \quad \xrightarrow{\text{Ar'}} \\
\text{Ar} & \quad \text{Ge} = \text{M(CO)}_5
\end{align*}
\]

Ar = Tb, Ar' = Tip, M = Cr, W
Tb = 2,4,6-tris[bis(trimethylsily1) methyl]phenyl
Tip = 2,4,6-trisopropylphenyl
Ar = Ar' = (2,4,6-tri-t-butylphenyl)seleno, M = W

The internally stabilized silylamide germyleane: Ge[N(SiMe\textsubscript{3})\textsubscript{2}]\textsuperscript{135} reacts with Ni and Pt phosphine complexes yielding Ni\textsuperscript{136} and Pt–germylene complexes (equation 35)\textsuperscript{137–139}.

\[
\begin{align*}
\text{Et}_3\text{P} & \quad \text{Pt(C}_2\text{O}_4) \quad + \quad \text{Ge}[\text{N(SiMe}_3\text{)}\textsubscript{2}] & \quad \xrightarrow{\text{benzene, -2CO}_2} & \quad \text{Et}_3\text{P} \\
\text{C}_2\text{O}_4 & \quad \text{oxalate}
\end{align*}
\]

A stable germyleane containing tetraaza macrocycle, i.e. dibenzotetraaza[14]annulene (tmtaa), and a variety of cyclic germyleanes (such as 30) readily act as two electron donors to form a variety of metal complexes\textsuperscript{101,140–144}.

\[
\begin{align*}
\text{N} & \quad \text{Ge} \quad \text{SiMe}_2 \\
\text{N} & \quad \text{t-Bu} \\
\text{N} & \quad \text{t-Bu}
\end{align*}
\]

Since 30 and related germyleanes have both a filled \(\sigma\)-donor orbital and a low-lying vacant \(\pi\)-orbital, they can act as \(\sigma\)-donor and/or \(\pi\)-acceptor ligands\textsuperscript{101}, and are the building blocks for the formation of unusual, and unpredictable, trimetallic or tetrametallic clusters. For example, the reaction of nickelocene with 30 resulted in the formation of 31, an unprecedented complex in which the two Cp ligands are bound differently and involve the rupture of \(\eta^5\)-bonding between Cp and Ni (equation 36). The two Ge atoms are also in different environments: one is trigonal planar with a short Ge–Ni double bond (2.085(3) Å) while the other is four-coordinated with tetrahedral geometry around Ge and a significantly longer bond between Ni and Ge [2.258(3) Å]\textsuperscript{143}.

\[
\begin{align*}
\text{Ni} + 30 & \quad \xrightarrow{\text{toluene, 80 °C}} \quad \text{Me}_2\text{Si} \\
\text{Me}_2\text{Si} & \quad \text{Ni} \quad \text{Ge} \\
\text{Ge} & \quad \text{Ni} \\
\text{SiMe}_2 & \quad \text{Ge} \\
\text{N} & \quad \text{t-Bu} \\
\text{N} & \quad \text{t-Bu}
\end{align*}
\]
A related cluster \(32\) is obtained from the reaction of \(30\) with \(\text{RhCl}((\text{PPh}_3)_3\). The central Rh has a square-planar arrangement of the four germanium atoms, with two short Rh–Ge bonds [average Rh–Ge bond length 2.337(1) \(\text{Å}\)] having multiple character and the other two Ge atoms [average Rh–Ge bond length (2.373 (2) \(\text{Å}\)] being tetracoordinate bridged by the chlorine atom\(^{142}\).

\[
\text{Ge} \quad \text{Rh} \quad \text{Ge} \\
\text{GeGe} \\
N \\
\text{SiMe}_2
\]

The Pt–Fe heterobimetallic complex \(33\) reacts reversibly with \(30\) to form \(34\), containing both terminal and bridging germylene ligands (equation \(37\))\(^{144}\).

\[
\begin{align*}
\text{Ph}_2\text{P} & \quad \text{PPh}_2 \\
\text{Ph}_3\text{P} & \quad \text{Pt} \quad \text{Fe} \\
& \quad \text{Ge} \quad \text{NBu-t} \\
& \quad \text{t-BuN} \quad \text{SiMe}_2
\end{align*}
\quad \xrightarrow{30 + \text{PPh}_3} 
\begin{align*}
\text{Ph}_2\text{P} & \quad \text{PPh}_2 \\
\text{Ph}_3\text{P} & \quad \text{Pt} \quad \text{Fe} \\
& \quad \text{Ge} \quad \text{NBu-t} \\
& \quad \text{t-BuN} \quad \text{SiMe}_2
\end{align*}
\]

(33) (34) (37)

An interesting (\(\mu\)-germylene)manganese complex \(\left[(\eta^5\text{-C}_5\text{H}_5)\text{Mn}((\text{CO})_2\right]_{2}(\mu\text{-GeCl}_2)\) \(35\) was obtained directly from the treatment of \(\left[(\eta^5\text{-C}_5\text{H}_5)\text{Mn}((\text{CO})_2\right] \cdot \text{THF} \) with \(\text{GeCl}_2 \cdot \text{dioxane}\) in a molar ratio of 2 : 1 in THF (equation \(37a\))\(^{145}\). Complex \(35\) undergoes reductive dehalogenation by zinc dust in the presence of \(\left[(\eta^5\text{-C}_5\text{H}_5)\text{Mn}((\text{CO})_2\right] \cdot \text{THF}\) to give a trinuclear germylene complex \(36\) previously synthesized by the photochemical treatment of \(\left[(\eta^5\text{-C}_5\text{H}_5)((\text{CO})_2\right]_{2}\text{Mn}={\text{Ge}}={\text{Mn}((\text{CO})_2)}(\eta^5\text{-C}_5\text{H}_5)\) in the presence of another molecule of \(\left[(\eta^5\text{-C}_5\text{H}_5)\text{Mn}((\text{CO})_2\right] \cdot \text{THF}\)\(^{57,58}\).

Base-free alkyl-substituted germyl(germylene)tungsten carbonyl complexes \(37\) and \(38\) were synthesized by the photolysis of digermyl complexes of tungsten \(39\) and \(40\) in benzene (equation \(38\)). These complexes are formed by the 1,2-germyl migrations after the initial photodissociation of CO from \(39\) and \(40\)\(^{146}\).
2. Cationic germylene complexes

Cationic germylene complexes are scarce and mononuclear cationic germylene complexes seem limited to only three examples. The cationic iron–germylene complexes 41 and 42 were synthesized by the abstraction of chloride from chlorogermyliron complexes 43 and 44 using a halogen abstracting agent in the presence of a donor molecule (equation 39)\(^{147a}\). A related rhenium complex, 45, was obtained from the exchange reaction of 46 with Me\(_3\)SiOTf (equation 40)\(^{33}\). The X-ray structure of 45 attributes a considerable ionic character to the germanium–triflate bond and double bond character to the germanium–rhenium bond. A variable-temperature-type NMR spectrum indicated that the diastereotopic phenyl groups in 45 coalesce at 268 K and suggest that it is in equilibrium with the cationic rhenium germylene complex 47.

\[ \text{R}_5 = \text{Me}_5 \]  
\[ \text{R}_5 = \text{Me}_4\text{Et} \]
A binuclear donor-stabilized cationic bridged germylene diiron complex \([\text{Cp}_2\text{Fe}_2(\text{CO})_3(\mu-\text{GeBu-t} \cdot \text{DMAP})]^+\text{OTf}^-, \) \(48\), of class VI was obtained from the exchange of an iodine atom on \(\mu\)-germylene bridge \(49\) by silver triflate in the presence of a strong base, 4-dimethylaminopyridine in acetonitrile (equation 41)\(^{147}\). The germanium atom of the \(\mu\)-germylene bridge is pyramidalized due to the coordination of the lone pair of the base. The Fe–Ge bond length of 2.322(2) Å is shorter than those for neutral germylene bridged diiron complexes, indicating a considerable double bond character in the iron–germanium bond.

Thermolysis of \([\text{Cp}_2\text{W}((\text{SiMe}_3))(\text{GeMe}_2\text{OTf})]\) \((50)\) in solution and in the solid state resulted in the formation of a binuclear cationic bridging germylene complex \(51\), type V (equation 42). Structural analysis shows two types of Cp rings and Ge atoms. One of the Ge atoms is tetracoordinated, with a long W–Ge bond [2.583(2) Å] comparable to the W–Ge single bonds. The other planar three-coordinate germanium has a short W–Ge bond of 2.487(2) Å, which suggests that the positive charge at the germanium atom is delocalized by back-bonding to the tungsten atom\(^{148}\).

3. Base-stabilized germylene complexes

As expected, base-free tungsten germylene complex \(37\) reacts with pyridine to afford the base-coordinated tungsten complex \(52\), \(\text{Cp'}\text{W}(\text{CO})_2(=\text{GeMe}_2 \cdot \text{py})(\text{GeMe}_3)\)\(^{146}\). The tungsten–germylene bond of 2.5279(6)Å in \(52\) is significantly longer than the tungsten–germylene bond of 2.4590(16)Å in \(37\).
The base-stabilized diiron germyl analog of allene 53, of class VII, was obtained from treatment of \([\text{Fe}(\text{CO})_4(\mu-\text{GeBr}_2)]_2\) with a pyridine–diethyl ether solution of \(\text{Na}_2\text{Fe}(\text{CO})_4\). The acute \(\text{N}−\text{Ge}−\text{N}\) bond angle of 89°, short \(\text{Fe}−\text{Ge}\) bonds (average 2.35 Å) and widening of the \(\text{Fe}−\text{Ge}−\text{Fe}\) angle to 131° demonstrate the multiple bonding between \(\text{Fe}\) and \(\text{Ge}\) in 53\(^\text{149}\).

\[
\text{py} \quad \text{py} \\
\begin{array}{c}
\text{(CO)}_4\text{Fe} \\
\downarrow \\
\text{Ge} \\
\downarrow \\
\text{Fe} \quad \text{(CO)}_4
\end{array}
\]

(53)

Intramolecularly alkoxy base-stabilized bis(germylene)-, 54, or (germylene)(silylene)-, 55, iron complexes, of type IV, were obtained from the photolysis of digermyl or germysilyl iron complexes (equation 43)\(^\text{14}\). These are the same type of complexes noted above for base-free tungsten analogs\(^\text{146}\) involving \(\alpha\)-elimination subsequent to photochemical elimination of CO as noted below.

\[
\begin{array}{c}

\text{GeMe}_2\text{EMe}_2\text{OMe} \\
\downarrow \\
\text{OC}
\end{array}
\]

(54) \(E = \text{Ge}\)

(55) \(E = \text{Si}\)

In the case of the iron system, base stabilization is required for their isolation. Variable temperature NMR studies suggest that the methoxy-bridged bis(silylene) complexes do not undergo the silylene rotation whereas bis(germylene) iron complexes undergo the germylene–methyl group exchange. A mechanism involving cleavage of the germium–oxygen bond followed by rotation of the germylene group to interchange the methyl groups reasonably explains the fluxional behavior of 54 and 55. This difference also reflects the greater stability of the M=Ge bond in comparison to the M=Si bond and the weaker Ge–O bond than the Si–O bond.
D. Synthesis of Transition Metal Germanium Triple Bond Germlyyne Complexes

Data on these compounds are collected in Tables 6 and 8. Stable mononuclear transition-metal germlyne complexes with a formal triple bond between the Ge and metal atoms (Cr, Mo, W, 56–62) have been synthesized by a combination of salt-elimination and decarbonylation reaction (equation 44)\(^{150,151}\). The decarbonylation process for the Cr and W intermediates can involve either a thermal or a photochemical reaction; the molybdenum germlyne complexes 56 and 57 were obtained directly, even at low temperatures.

![Diagram](image)

\[ \text{(56)} M = \text{Mo, Ar} = 2,6\text{-bis(Mes)phenyl} \\
\text{(57)} M = \text{Mo, Ar} = 2,6\text{-bis(triisopropylphenyl)phenyl} \\
\text{(58)} M = \text{Cr, Ar} = 2,6\text{-bis(triisopropylphenyl)phenyl} \\
\text{(59)} M = \text{W, Ar} = 2,6\text{-bis(triisopropylphenyl)phenyl} \\
\text{(60)} M = \text{W, Ar} = 2,6\text{-bis(Mes)phenyl} \\
\]

Ar = 2, 6-bis(triisopropylphenyl)phenyl

The metal–germanium bond distances in 58 [2.1666(4) \( \text{Å} \)] and 60 [2.2767(14) \( \text{Å} \)] are \( \text{ca} \sim 0.41 \text{ Å} \) shorter than the M–Ge bond distances in the metallogermlynes 61 and 62. The metal germlynes have almost linear (M–Ge–C) angles in the range of 170.9(3)–175.99(6) whereas the (M–Ge–C) bond angles of metallogermlynes 61 and 62 are bent at 114.7(6)\( ^{5} \) and 117.8(2)\( ^{5} \), respectively. These structural features strongly suggest a formal triple bond between the 15-electron \( (\eta^{5}\text{-C}_{5}\text{H}_{5}\text{M})\text{(CO)}_{2} \) fragment and the Ge–Ar moiety.

E. The Reactivity of the Transition Metal Germanium Single Bond

1. Cleavage reactions

The cleavage of the metal–germanium bond occurs under mild conditions with both electrophilic and nucleophilic reagents. Halogens, halogen acids, organic halides, phenyllithium, Grignard reagents, \( \text{H}_{2} \) and lithium aluminum hydride easily cleave the Pd–Ge \(^{33} \), Pt–Ge \(^{44–46,111} \), Mo–Ge \(^{28,53} \), W–Ge \(^{28} \) and Co–Ge \(^{19,59} \) bonds. Mercuric salts also cleave the Mo–Ge and W–Ge bonds with the formation of M–Hg bonds (equation 45)\(^{28} \).
Such cleavage reactions of Pt−Ge complexes are believed to proceed through oxidative addition and a reductive elimination mechanism involving octahedral Pt (IV) complex (equation 46). In methyl/phenyl mixed germyl platinum complexes, selective cleavage of the Me₃Ge group occurred in preference to cleavage of a Ph₃Ge group. The M−Ge bond of the group 11 complexes, (R₃P)ₙM−GePh₃ (M = Cu, Ag, Au), are readily cleaved by 1,2-dibromoethane producing ethylene, Ph₃GeBr and R₃PMBr. Cleavage reactions of M−Ge bonds suggest that their stability order is Au−Ge > Ag−Ge > Cu−Ge.

The zirconocene complex, CpCp*Zr−GePh₃(Cl) undergoes hydrogenolysis of the Zr−Ge bond, giving zirconocene hydrochloride and triphenylgermane. The reaction is slow in comparison with the hydrogenolysis of the Zr−Si bond in an analogous complex (equation 47).

The germanium heterocycles of Co, Fe and Ru also undergo cleavage of the M−Ge bond with halogens, alcohols, organic halides, metal halides, PbCl₂, HgCl₂ and Bu₃SnH.
17. Transition metal complexes of germanium, tin and lead

They also react with 1,2-quinone through a radical process with the expulsion of metal carbonyls to form dioxo-metallacycles, the adducts of the biradicals \( \text{Me}_2\text{Ge}-(\text{CH}_2)_n-\text{GeMe}_2 \) \( (n = 1, 2) \) with quinones:\textsuperscript{75–79}

\[
\text{PbCl}_2 \quad \text{Me}_2\text{ClGe}(\text{CH}_2)_n\text{GeClMe}_2 + \text{M}_3(\text{CO})_{12} + \text{Pb}
\]

\[
\text{Me}_2\text{XGe}(\text{CH}_2)_n\text{GeXMe}_2
\]

\[
\text{Me}_2\text{HGe}(\text{CH}_2)_n\text{GeHMe}_2
\]

\[
\text{Me}_2(\text{OMe})\text{Ge}(\text{CH}_2)_n\text{Ge}(\text{OMe})\text{Me}_2 + \text{M}_3(\text{CO})_{12}
\]

\[
(M = \text{Fe}, \text{Ru})
\]

(48)

2. Metal digermyl, germylsilyl and germylstannyl complexes

Data on these compounds are given in Table 3.

Transition-metal complexes with direct metal–germanium bonds in which the germanium atom is also bonded to another group 14 element are of considerable interest. They are readily formed by salt-elimination reaction involving a transition metallate and the appropriate chlorogermyl compound (equation 49)\textsuperscript{13,15}. The complexes are thermally stable and may be handled in air for limited periods; however, they exhibit photochemical behavior reminiscent of that of the related oligosilyl complexes. Thus, subsequent to initial CO elimination followed by an \( \alpha \)-elimination of the silyl (or stannyl) group silyl (stannyl) germylene transients are formed. These can undergo a series of 1,3-migrations to form the isomeric germyl silylene (stannylene) complexes. Final elimination of the group 14 carbene analog upon recoordination of CO results in the formation of a mono-group 14 substituted metal compound, \( \text{Fe} = (\eta^5-\text{C}_5\text{H}_5)\text{Fe(CO)}_2 \) (equation 50).

As noted above, this reaction is very specific since, regardless of the initial complexes used, \( \text{FeGeMe}_2\text{SiMe}_3 \) or the isomeric \( \text{FeSiMe}_2\text{GeMe}_3 \), only the \( \text{FeSiMe}_3 \) compound is obtained. The greater stability for \( \text{Ge(II)} \) vs \( \text{Si(II)} \) intermediate compounds can be used to understand this selectivity, coupled to the greater thermodynamic driving force for the formation of \( \text{Si–C} \) vs \( \text{Ge–C} \) bonds. The 1,3-alkyl group migration is thus unidirectional, favoring the formation of the germylene complex.

In the case of the \( \text{FeGeMe}_2\text{SnMe}_3 \), this compound rearranges prior to loss of the group 14 carbene analog to form \( \text{FeSnMe}_2\text{GeMe}_3 \). This illustrates the more or less equal stability of the stannylene and germylene intermediates, as may be expected.

\[
\text{OC} \quad \text{Fe} \quad \text{Na}^+ \quad \text{ClGeMe}_2\text{SiMe}_3 \quad \text{OC}
\]

\[
\text{Fe} \quad \text{GeMe}_2\text{SiMe}_3 \quad \text{OC}
\]

(49)
3. Chemistry at the metal center

A series of transition-metal carbene complexes can be obtained from the neutral and anionic transition-metal germanium complexes. Treatment of \((\eta^5\text{-C}_5\text{H}_5)M(\text{CO})_3\text{−GePh}_3\) with organolithium reagents followed by alkylation resulted in the formation of a series of carbene compounds, \((\eta^5\text{-C}_5\text{H}_5)M(\text{CO})_3\text{−GePh}_3\text{C}(\text{OR}_1\text{)}\text{R}\) (equation 51)\(^{152,155}\). Carbene complexes can be obtained in a single step by the direct reaction of anionic germyl transition-metal complexes with dichlorocyclopropene by a substitution reaction\(^{154}\).

4. Intramolecular migration of the germyl group from the metal center

In some of the carbene formation chemistry noted above, a secondary reaction has been observed. Thus, treatment of \((\eta^5\text{-C}_5\text{H}_5)M(\text{CO})_n\text{GeR}_3\) (M = Mo, W, \(n = 3\); M = Fe, \(n = 2\)) with bases such as LDA, MeLi etc., followed by alkylation with RX, resulted in the formation of a series of products derived from germyl migration to the cyclopentadienyl ring, \([(\eta^5\text{-C}_5\text{H}_4\text{GeR}_3)M(\text{CO})_n\text{R}]\) (equation 52)\(^{153,155}\).

5. Photolysis/thermolysis of metal carbonyl germyl complexes

Photolysis of mononuclear chlorogermyl metal carbonyl complexes yields binuclear bis(\(\mu\)-germylene) metal carbonyl compounds (equation 53). The dimerization is believed to occur through a radical process\(^8\).
The photolysis of the related chlorogermyl iron complex, FpGeMe2Cl, mainly gives \( 63 \), which exist as a 4 : 1 mixture of the cis and trans isomers in solution\(^8,156,157\). Photolysis of the bimetallic \([\text{CpFe(CO)}_2\text{]}_2\text{GeMe}_2\) also yields \( 63 \) and such chemistry is typical of many such bimetallic germyl complexes (equation 54)\(^8,16,156–159\). In contrast, the related molybdenum complex, \([\text{CpMo(CO)}_3\text{]}_2\text{GeMe}_2\), simply undergoes cleavage of the Mo–Ge bond on photolysis\(^8\). The dynamic NMR and structure of \( 63 \) was reported and nonbridged terminal germylene intermediates were proposed to rationalize its cis–trans isomerization in solution\(^159\).

\[
\text{ML}_n(\text{CO})-\text{GeMe}_2-\text{ML}_n(\text{CO}) \xrightarrow{\text{hv}} \text{L}_n\text{M} \quad (54)
\]

\[
\text{ML}_n = \text{Co(CO)}_3, \text{Mn(CO)}_5
\]

Photolysis of the bimetallic iron complex FpGeMe2SiMe2Fp, \( 64 \), selectively gives a (\( \mu \)-germylene)(\( \mu \)-carbonyl) diiron complex \( 65 \) as a mixture of three equilibrating geometrical isomers. Prolonged photolysis of \( 65 \) transforms it to a mixture of cis and trans isomers of (\( \mu \)-germylene)(\( \mu \)-silylene) diiron complex \( 66 \) (equation 55)\(^15\). The proposed mechanism involves germylene and silylene intermediates and is closely related to the photochemical transformations of the disilyl diiron complex, FpSiMe2SiMe2Fp\(^{160,161}\).

A binuclear bis(\( \mu \)-germylene) osmium carbonyl complex \([\text{(OC)}_4\text{Os(GeMe}_2\text{)}]\)_2 on photolysis or thermolysis yields a mixture of an interesting series of (\( \mu \)-germylene) osmium clusters\(^36\). Bis(metalcarbonyl)germacyclopentene complexes on photolysis or thermolysis
also undergo a loss of CO with the formation of a carbonyl-bridged metal–metal bond (equation 56)\(^9\)\(^{162}\); thermolysis of the related Mn complex results in the cleavage of Ge–C bonds with the extrusion of a metal germylene which can be trapped with dienes\(^9\)\(^a\).

\[
\begin{align*}
\text{Fe} & \quad \text{GeMe}_2\text{SiMe}_2 & \quad \text{Fe} \\
\text{OC} & \quad \text{OC} & \quad \text{OC} \\
(64) & \quad (65)
\end{align*}
\]

6. Reactivity of germa-heterocycles

Bis[(dimethylgermyl)methane]metal carbonyls \((M = \text{Fe, Ru})\) undergo facile ring expansion with aldehydes\(^{73,75–79}\). The reactions occur faster under UV light and 1,2-insertions resulting in the ring expansion occur almost quantitatively (equation 57). The six-membered metallacycles are stable at room temperature but decompose thermally into a mixture of alkenes, germanium oxides and metal carbonyls. The proposed mechanism involves initial loss of CO under photolytic conditions, coordination of aldehyde to the metal center, insertion of the carbonyl group of the aldehyde into the metal–germanium bond and finally the recoordination of CO to form the metallacycles.

\[
\begin{align*}
\text{ML}_n & = \text{Mn(CO)}_4, \text{CpFe(CO)}, \text{Co(CO)}_3 \\
\text{ML}_n & = \text{Mn(CO)}_5 \\
\end{align*}
\]
F. Chemistry of the Transition Metal Germanium Double Bond, $M=\text{Ge}$

The platinum germylene complex 67 has been extensively studied and an array of interesting chemistry has been developed. The chemistry, outlined in equation 58, is predominantly addition to the $M=\text{Ge}$ bond, e.g. to give 68–71. The rearrangement of the 1,2-dioxametallocycle in 68 to the 1,3 isomer 72 is understood in terms of forming two $M-O$ bonds at the expense of the relatively weak $O-O$ bond\textsuperscript{136–139}.

*a*Cp²⁺ = A mono ethyl-substituted Cp.
There have been several significant reviews of this area of chemistry\textsuperscript{5}. It is the purpose of this review to summarize primarily the synthesis and reactivity of transition metal–tin complexes, with emphasis on the activity since the last of the previous reviews in 1989, and those aspects not previously covered.

A. Synthesis of the Transition Metal Tin Single Bond

1. Salt-elimination reactions between transition metal anions and tin halides

Examples of the use of the salt-elimination reaction between an alkali metal transition metallate and haloorganotin compounds, usually the chlorides, can be found for almost each group of the transition elements and has been widely used since the initial studies on transition-metal tin chemistry. The resulting complexes can be neutral or anionic as noted in the representative selection illustrated in equations 59–61 and usually result in good yield transformations. Indeed, a large number of such complexes have been synthesized for the purposes of proving the existence of the various metallate systems, such as the efficiency of the process and the general stability of the resulting complexes. The method works well for the characterization of highly reduced metal carbonyl anions including those of Ti, Cr, Mo and W\textsuperscript{184–187}.

\[
[Ti(CO)_{6}]^{2-} + ClSnR_{3} \longrightarrow [R_{3}SnTi(CO)_{6}]^{-}
\]

\(R = Me, Ph, Cy\) \hspace{1cm} (59)

\[
[M(CO)_{5}]^{2-} + ClSnR_{3} \longrightarrow [(CO)_{5}MSnR_{3}]^{-}
\] \(M = Cr, Mo, W; R = Me, Ph\) \hspace{1cm} (60)

\[
[M(CO)_{4}]^{-4} + ClSnPh_{3} \longrightarrow cis-[(CO)_{4}M(SnPh_{3})_{2}]^{-2}
\] \(M = Cr, Mo, W\) \hspace{1cm} (61)

New group 4 cyclopentadienylmetal carbonylate derivatives were also reported (equation 62)\textsuperscript{188,189}.

\[
[Cp^{R}M(CO)_{4}]^{-} + ClSnPh_{3} \longrightarrow Cp^{R}(CO)_{4}MSnPh_{3}
\] \(M = Ti, Zr; R = H, Me\) \hspace{1cm} (62)

Of particular interest is the capacity to utilize hydridometallate salts to form bifunctional stannyl(hydrido) metal derivatives (equation 63)\textsuperscript{190}.

\[
Li[Cp_{2}NbH_{2}] + ClSnMe_{3} \longrightarrow [Cp_{2}NbH_{2}SnMe_{3}]
\] \hspace{1cm} (63)

\(\pi\)-Arene metal carbylnates react both with the maintenance of the aromatic ring (equations 64\textsuperscript{191} and 65\textsuperscript{192}) but there are also examples in which they are transformed to an \(\eta^{5}\)-cyclohexadienyl group (equation 66)\textsuperscript{193}.

\[
[(\eta^{6}-C_{6}H_{6})Cr(CO)_{2}]^{-2} + ClSnPh_{3} \longrightarrow [(\eta^{6}-C_{6}H_{6})(CO)_{2}Cr(SnPh_{3})_{2}]^{-}
\] \hspace{1cm} (64)

\[
[(\eta^{6}-arene)(CO)_{2}CrSnPh_{3}]^{-} + ClSnMe_{3} \longrightarrow [(\eta^{6}-arene)(CO)_{2}Cr(SnPh_{3})(SnMe_{3})]
\] \hspace{1cm} (65)
The salt-elimination reactions are usually performed in THF or related ethereal solvents and the range of metallates is very large. The method continues to be useful as noted from the additional recent examples collected in Table 10.

In general these salt-elimination reactions are straightforward, however, an occasional surprise is noted. For example, the reaction of \([\text{PPh}_3)_2\text{Mn(CO)}_3^-\) with BrSnMe\(_3\) gives a mixture of fac-cis and mer-trans isomers of \([\text{PPh}_3)_2\text{Mn(CO)}_3\text{SnMe}_3\) at room temperature\(^{219}\), but in refluxing THF \([\text{PPh}_3)_2\text{(CO)}_3\text{MnSnMe}_2\text{Br}\] is obtained, illustrating the weakness of the Sn–C bond\(^{220}\).

Salt-elimination reactions also produce multimetal complexes, e.g. 73 (equation 67)\(^{221}\).

\[
\text{Na}_2[\text{Os(CO)}_4] + \text{R}_2\text{SnCl}_2 \xrightarrow{-2 \text{NaCl}} \text{R}_2\text{Sn} \begin{array}{c}\text{Os(CO)}_4\end{array} \text{Sn} \begin{array}{c}\text{Os(CO)}_4\end{array}\]  

(67)

R = Me, Ph

Unprecedented twelve-membered metallocycle Os\(_6\)Sn\(_6\) 74 is formed from the reaction between Na\(_2\)[Os(CO)]\(_4\)] with Cl\(_2\)SnPh\(_2\) in THF\(^{222}\).

Dimetallate salts can also be used to form extended metal–metal bonded complexes. Thus, the reactions of K\(_2\)[Fe\(_2\)(CO)]\(_8\)] with ClSnPh\(_3\) and Cl\(_2\)SnPh\(_2\) gave Ph\(_3\)Sn(CO)]\(_4\)Fe–Fe(CO)]\(_4\)SnPh\(_3\) and ClPh\(_2\)Sn(CO)]\(_4\)Fe–Fe(CO)]\(_4\)SnPh\(_2\)Cl, respectively (equation 68)\(^{223}\).

Transition metal–tin clusters can be formed from similar reactions and K\(_2\)[Fe\(_3\)S(CO)]\(_9\)] mixed with Me\(_2\)SnBr\(_2\) resulted in the formation of a double-bridged cluster 75. Similarly,

\end{align*}
\]

(69) $E = S$

(75) $E = PR, R = \text{Ph, } p$-Tol

Reduction of (butadiene)Fe(CO)$_3$ and (1-Ph-butadiene)Fe(CO)$_3$ with Li[HBEt$_3$] in THF, followed by treatment with ClSnMe$_3$, afforded (anti-methallyl)(CO)$_3$FeSnMe$_3$ and (anti-1-Me-syn-3-Ph-allyl)(CO)$_3$FeSnMe$_3$, which thermally isomerized to their syn isomers (equations 70 and 71)$^{225}$.

\end{align*}
\]

(71)

As noted above, the lability of the Sn–C bond is often a factor determining the outcome of such reactions and this is well illustrated in a very early reaction between Na$_2$[Fe(CO)$_4$] with MeSnCl$_3$, where redistribution of methyl groups took place to form 77 and 78$^{226}$. An unusual hypercoordinated tin compound 79 was obtained by reacting K[Fe(CO)$_3$[Si(OMe)$_3$][Ph$_2$P(2-pyridyl)] with Cl$_2$SnPh$_2$, which involved an unusual silicon–tin exchange$^{227}$.

\[

\text{Sn} & \xrightarrow{\text{Me}_2\text{Sn}} \text{Sn}
\end{align*}
\]

(78)
The ferrate-borole derivative \( [(C_4H_4BPh)Fe(CO)_2(SnPh_3)]^- \) (as tetraethylammonium salt) was obtained from the anion \( [(C_4H_4BPh)Fe(CO)_2]^- \), and similarly the 1,1-dimethylsilole and 1,1,3,4-tetramethylsilole (L) derivatives \( [(\eta^4-L)Co(CO)_2]_2 \) can be converted to anions, which react with ClSnPh_3 to form derivatives \( (\eta^4-L)(CO)_2CoSnPh_3 \). Cobalt derivatives of some tin-containing cyclosiloxanes, 80 and 81, were prepared from the corresponding Sn–Cl compounds by similar procedures, using \([Co(CO)_4]^-\). The reaction of the cluster \([Ni_6(CO)_{12}]^-\) with trialkyltin halides form \([Ni(SnRCl_2)_4(CO)]^-\) (R = Me, Bu), which are precursors of polynuclear \([Ni_{11}(SnR)_2(CO)_{18}]^-\), based upon a Ni-centered Ni_{10}Sn_2 icosahedral cage.

2. Synthesis from transition metal complexes and organotin anions

Triorganotin salts of general formula \([R_3Sn]^+\), A = alkali metal, are readily obtained from the reaction of the corresponding chlorotin compounds with the alkali metal. Reaction of these compounds with transition-metal halides is thus another useful salt-elimination reaction for the formation of tin–metal bonds. A representative selection of such reactions is illustrated in equation 72–74.

\[
\begin{align*}
\text{LiSnR}_3 + [\text{CIM(CO)}_5][\text{NEt}_4]^+ & \rightarrow [(\text{CO})_5\text{MSnR}_3][\text{NEt}_4]^+ \quad (72) \\
\text{M} = \text{Cr, Mo, W}; \ R = \text{Me, Ph} \\
\text{LiSnPh}_3 + \text{Cp}_2\text{MCl}_2 & \rightarrow \text{Cp}_2\text{M(SnPh}_3)\text{Cl} \quad (73) \\
\text{Cp}' = \text{C}_5\text{H}_5, \text{C}_5\text{Me}_5; \ M = \text{Zr, Hf} \\
\text{LiSnPh}_3 + \text{M}_2\text{Cl}_2(\text{NMe}_2)_4 & \rightarrow (\text{Me}_2\text{N})_4\text{M}_2(\text{SnPh}_3)_2 \quad (74) \\
\text{M} = \text{Mo, W}
\end{align*}
\]
A similar reaction involves the use of transition-metal complexes containing other good leaving groups, or systems that can readily provide increased coordination numbers by accommodating the Lewis base tin nucleophile, \([R_3Sn]^{-}\). The latter reactions usually lead to metal–tin bonds in anionic metallate products, as illustrated in equations 75 and 76 using sodium triphenyltin\(^{233,234}\).

\[
\text{NaSnPh}_3 + \text{Ti(CO)}_5(\text{dmpe}) \rightarrow [\text{Na}]^+[\text{Ph}_3\text{SnTi(CO)}_5(\text{dmpe})]^-
\]

\[
\text{NaSnPh}_3 + \text{MCl}_4 \cdot 2\text{THF} + \text{CO} \rightarrow [\text{Na}^+]_2[(\text{Ph}_3\text{Sn})_2\text{M(CO)}_4]^-
\]

\(M = \text{Zr, Hf}\)

In the case of copper complexes, the use of organotin lithium salts provided a route to the coordination of the stannylate system to neutral Cu(I) to form the corresponding cuprates (equations 77\(^{235}\) and 78\(^{236}\)).

\[
\text{LiSnPh}_3 + \text{CuPh} \rightarrow [\text{Li}]^+[\text{PhCuSnPh}_3]^{-}
\]

\[
\text{LiSnMe}_3 + \text{CuSPh} \rightarrow [\text{Li}]^+[\text{PhSCuSnMe}_3]^{-}
\]

Trimethylstannyl potassium, \(\text{KSnMe}_3\), reacts with bis(naphthalene)titanium(0) (obtained by reducing \(\text{TiCl}_4 \cdot 2\text{THF}\) by \(\text{KC}_{10}\text{H}_8\)) to give \([\text{Ti(C}_{10}\text{H}_8)_2(\text{SnMe}_3)_2]^{2-}\) in very good yield\(^{237}\). Solutions containing equimolar concentrations of \(\text{LiMe, LiSnMe}_3\), and \(\text{CuCN}\), or the reaction products of \(\text{Sn}_2\text{Me}_6\) with \(\text{Li}_2[\text{Me}_2\text{Cu(CN)}]\) form higher order stannylcuprates \(\text{Me}_3\text{Sn(Me)Cu(CN)}_2\text{Li}_2\), useful as reagents for delivering \(\text{SnMe}_3\) groups to various substrates\(^{238}\).

### 3. Elimination of \(\text{H}_2\), HCl, amines, hydrocarbons, silanes, etc.

The well-established reducing properties of the \(\text{Sn–H}\) bond have led to a number of useful synthetic methods for forming a tin–metal bond. In particular, many early transition-metal hydrides, -amides and -silanes readily eliminate \(\text{H}_2/\text{amines/silanes}\) upon treatment with the \(\text{Sn–H}\) bond. Some examples are illustrated in equations 79–83 for titanium\(^{232,239a}\), zirconium\(^{232}\), niobium\(^{239b}\) and manganese\(^{239c}\) complexes.

\[
\text{Cp^*_2TiH} + \text{HSnPh}_3 \rightarrow \text{Cp^*_2SnTiPh}_3 + \text{H}_2
\]

\[
(Et_2\text{N})_2\text{Ti(OBu-t)}_2 + 2 \text{HSnBu}_3 \rightarrow (\text{Bu}_3\text{Sn})_2\text{Ti(OBu-t)}_2 + 2 \text{Et}_2\text{NH}
\]

\[
\text{CpCp’Zr[Si(SiMe)_3]Cl + HSnPh}_3 \rightarrow \text{CpCp’Zr(SnPh}_3\text{Cl + (SiMe}_3\text{)_3SiH}
\]

\[
\text{HSnPh}_3 + [(\text{Me}_3\text{SiC}_5\text{H}_4)_2\text{NbH}_3] \rightarrow [(\text{Me}_3\text{SiC}_5\text{H}_4)_2(\text{H})_2\text{NbSnPh}_3]
\]

\[
\text{Mn}_2(\text{CO})_8\text{L}_2 + \text{HSnBu}_3 \rightarrow 2(\text{CO})_4\text{LMnSnBu}_3 + \text{H}_2
\]

\(L = \text{CO, PR}_3; R = \text{Me, Bu, i-Pr}\)

An unusual reaction, with loss of a phenyl group from \(\text{HSnPh}_3\), occurs with some dinuclear manganese–hydride carbonyl complexes (equation 84)\(^{240}\). The chemistry outlined in the previous equations, involving elimination of \(\text{H}_2\), occurs in many regions of the periodic table and produces good yields of the metal–tin bonded complex.
Related reactions involving elimination of hydrocarbons are also known, but appear much less general and this route has been used mostly for vanadium\textsuperscript{105}, zinc\textsuperscript{241a,241b}, cadmium\textsuperscript{241c} and mercury\textsuperscript{242} derivatives (equations 85–89).

\[
\begin{align*}
\text{HSnEt}_3 + \text{Cp}_2\text{VCH}_2\text{CH}_2\text{SiMe}_3 & \rightarrow \text{Cp}_2\text{VSnEt}_3 + \text{EtSiMe}_3 \quad (85) \\
\text{EtZnCl} + 2 \text{HSnPh}_3 & \rightarrow \text{Zn(SnPh}_3)_2 + \text{C}_2\text{H}_6 + \text{HCl} \quad (87) \\
\text{Et}_2\text{Cd} + 2 \text{HSn(CH}_2\text{SiMe}_3)_3 & \rightarrow \text{Cd[Sn(CH}_2\text{SiMe}_3)_3]}_2 + \text{C}_2\text{H}_6 \quad (88) \\
\text{R} = \text{Me, Et, Pr, Bu}, & \text{ Ph} \\
\text{Hg(Bu-t)}_2 + 2 \text{HSnR}_3 & \rightarrow \text{Hg(SnR}_3)_2 + 2\text{r-BuH} \quad (89)
\end{align*}
\]

The elimination reaction between metal hydrides and tin halides is another useful route to the formation of the tin–metal bond (equations 90 and 91)\textsuperscript{243,244,294}. The presence of a base to remove the hydrogen halide is often necessary to prevent decomposition reactions.

\[
\begin{align*}
\text{X}_n\text{SnR}_{4-n} + \text{CpNbH}_3 & \rightarrow [\text{Cp}_2(\text{H})_2\text{NbSnR}_n\text{X}_3-n] \quad (90) \\
\text{R} = \text{Me, X} = \text{Cl, n} = 2, 3; \text{R} = \text{Et, X} = \text{Br, n} = 2 \\
2\text{Cl}_2\text{SnMe}_2 + \text{Cp}_2\text{WH}_2 + 2 \text{NEt}_3 & \rightarrow \text{Cp}_2\text{W(SnMe}_2\text{Cl})_2 + 2 \text{Et}_3\text{N-HCl} \quad (91a) \\
(\text{Cp}_2\text{Zr})_4 + 4 \text{Me}_3\text{SnCl} & \rightarrow [\text{Cp}_2\text{ZrSnMe}_3]_2 + 2\text{Cp}_2\text{ZrCl}_2 + (\text{Me}_3\text{Sn})_2 \quad (91b)
\end{align*}
\]

The elimination of amines may also be accomplished by using the reactions of organotin amides and transition-metal hydrides, or transition-metal amides and tin hydrides\textsuperscript{4}. Neither route has attracted much attention recently.

There are few elimination reactions involving oxygen-containing leaving groups. One interesting example is the loss of water that occurred when $[\text{L(CO)}_4\text{WH}]^-$, $\text{L} = \text{CO, P(OMe})_3$, reacted with $\text{Ph}_3\text{SnOH}$ to form $[\text{L(CO)}_4\text{WSnPh}_3]^-$. The presence of a base is often necessary to prevent decomposition reactions.

4. Addition of HSnR\textsubscript{3} to metal centers and related reactions

The addition of the Sn–H bond to a transition-metal center can lead to the formation of metal–tin bonds and this route has been widely investigated recently. In some cases the M–H bond is retained, while in others further chemistry is observed. Such reactions can be likened to oxidative addition reactions that can occur with and without the loss of ligands from the metal center. Some representative examples, involving chromium,
molybdenum and tungsten, iron, ruthenium, osmium, rhodium, and iridium complexes, are provided in equations 92–99.

\[
[(L)(CO)_4W(THF)] + HSnR_3 \rightarrow [(L)(CO)_4W(H)SnR_3]
\]  
(L = PPh_3, PPh_2Me; M = Cr, Mo, W; R = Me, Ph)

\[
[CpFe(CO)_2]_2 + HSnBu_3 \rightarrow Cp(CO)_2FeSnBu_3 + Cp(CO)Fe(H)(SnBu_3)_2
\]  
Fe(CO)_2[P(OPh)_3]_2 + HSnR_3 \rightarrow cis-[(PhO)_3P]_2(CO)_2(H)FeSnR_3
\]  
R = Me, Ph

\[
M(CO)_2(PPh_3)_3 + HSnR_3 \rightarrow R_3SnM(H)(CO)_2(PPh_3)_2
\]  
M = Ru, Os; R = p-Tol

\[
OsCl(NO)(PPh_3)_2 + HSnR_3 \rightarrow R_3SnOsH(Cl)(NO)(PPh_3)_2
\]  
R = p-Tol

\[
CpOsCl(PPr_i)_2 + HSnR_3 \rightarrow CpOsH(Cl)(PPr_i)SnR_3
\]  
R = Bu, Ph

\[
RhH(PPh_3)_4 + HSnR_3 \rightarrow Rh(H)((\mu-H)(SnR_3)_2)(PPh_3)_2 \rightarrow
\]  
R = Bu, Ph

\[
IrH(PPh_3)_2 + 2 HSnPh_3 \rightarrow
\]  
Ph_3Sn

Of particular interest with respect to addition of the Sn−H bond are the reactions of tin hydrides with areneM(CO)_3 (M = Cr, Mo, W) complexes. In these reactions the Sn−H bond coordinates to the metal in the \(\eta^2\)-fashion as illustrated for Cr in equation 101.

The reducing power of the Sn−H bond can interfere with oxidative additions when metal-halogen bonds are present. For example, the reaction of cis- or trans-CpRe(CO)_2Br_2 with HSnPh_3 yielded the dihydride CpRe(CO)_2H_2 and BrSnPh_3.
When the same reaction was performed in the presence of pyridine or Et₃N, trans-Cp(CO)₂Re(SnPh₃)₂ was obtained²⁵⁷.

\[
\text{Me} \quad \text{Me} \quad \text{Cr(CO)₃} \quad + \quad \text{HSnPh₃} \quad \xrightarrow{\text{hv} - \text{CO}} \quad \text{Me} \quad \text{Me} \quad \text{Me} \quad \text{Me} \quad \text{Cr} - \text{H} \quad \text{Sn Ph₃}
\]

(101)

\[
\text{Me} \quad \text{Me} \quad \text{Me} \quad \text{Cr(CO)₃} \quad + \quad \text{HSnPh₃} \quad \xrightarrow{\text{hv} - \text{CO}} \quad \text{Me} \quad \text{Me} \quad \text{Me} \quad \text{Me} \quad \text{Cr} - \text{H} \quad \text{Sn Ph₃}
\]

(82)

The reactions of tin hydrides with metal–metal bonded clusters has proven to be a successful route to a range of metal–tin bonded complexes. Products usually result in the cleavage of the M–M bond; however, under special conditions, for example with bridging ligands, the bond can remain intact and result in either bridging or terminal tin groups, as shown for some ruthenium²⁵⁸ and osmium²⁵⁹ clusters (equations 102 and 103).

\[
[Ru₃(μ-praz)(μ-CO)₃(CO)₁] + 2 \text{HSnR₃} \rightarrow
\text{praz} = \text{pyridazine}; R = \text{Bu}, \text{Ph}
\]

(102)

\[
\text{Os₃(μ-H)₂(CO)₁₀ + 2 HSnMe₃} \rightarrow \text{Os₃(μ-H)₂(CO)₁₀(SnMe₃)₂}
\]

(103)

Displacement of MeCN from M₃(CO)₁₂₋₈(MeCN)ₙ (M = Ru, Os; n = 1, 2) by organotin hydrides affords M₃(H)(CO)₁₁(SnR₃) (M = Ru, Os; R = alkyl, aryl) and Os₃(H)(CO)₁₀(MeCN)(SnR₃)²⁶⁰, as shown below.

\[
\begin{array}{c}
\text{(CO)}₄\text{M} \\
\text{H} \\
\text{SnR₃}
\end{array}
\quad \xrightarrow{\text{MeCN}} 
\begin{array}{c}
\text{(CO)}₄\text{Os} \\
\text{H} \\
\text{SnR₃}
\end{array}
\]

Similar displacement of ethylene from Cp*M(C₂H₄)₂ by HSnR₃ (M = Rh, Ir; R = Me, Bu) afforded Cp*M(H)₂(SnR₃)₂ (equation 104). An intermediate Cp*Ir(H)(SnR₃) (C₂H₄) was identified spectrally, and the same product was obtained from the reaction of the tin hydride with Cp₂*M₂Cl₄ (equation 105)²⁶¹.

\[
\text{Cp}^*\text{M(C₂H₄)₂ + 2 HSnR₃} \rightarrow \text{Cp}^*\text{M(H)₂(SnR₃)₂ + 2 C₂H₄}
\]

(104)

\[
\text{M} = \text{Rh, Ir}; R = \text{Me, Bu}
\]

\[
\text{Cp}^*\text{M₂Cl₄ + 4 HSnR₃} \rightarrow 2 \text{Cp}^*\text{M(H)₂(SnR₃)₂ + 4HCl}
\]

(105)
There are many individual reactions of tin hydrides with metal complexes that are not readily categorized. For example, the salt \([\text{Ru}_3(\mu\text{-NO})(\text{CO})_{10}]^-[\text{PPN}]^+\) reacts with one or two equivalents of HSnR₃ to form the oxidative addition products \(83\) and \(84\) (R = Bu, Ph) (equation 106)[262]. Similarly, the reaction between \(\text{RuH}(\eta^2\text{-H}_2\text{BH}_2)(\text{CO})(\text{P(Pr-i)}_3)\) and HSnPh₃, in a 1:3 molar ratio under a hydrogen atmosphere, results in the formation of \(85\) in which the \(\text{H}_2\) ligand can be easily displaced by \(\text{CO}\) or \(\text{P(OMe)}_3\) (equation 107).

\[
\begin{align*}
\text{CO} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO}
\end{align*}
\]

\(83\)

\[

\text{CO} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO}
\end{align*}
\]

\(84\)

\[
\begin{align*}
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO} \\
\text{OC} & \quad \text{Ru} \quad \text{CO}
\end{align*}
\]

\(85\)

The borohydride reduction of BrRe(CO)₅ in the presence of PPhMe₂ and HSnBu₃ forms (CO)₄Re(PMe₂Ph)H. The tin hydride adduct could not be isolated, but upon water work-up a cyclic dirhenium distannoxane \(86\) was isolated[264].

\[
\begin{align*}
\text{(CO)}_4\text{Re} & \quad \text{Re(CO)}_4 \\
\text{Bu}_2\text{Sn} & \quad \text{SnBu}_2
\end{align*}
\]

\(86\)

5. Insertion of Sn(II) species into \(M-X\) bonds

The stability of Sn(II) compounds led to their use to form Sn(IV) derivatives of the transition metals via insertion reactions (equations 108[253], 109, 110[49,265] and 111[164]),

\[
\text{Cp}_2(\text{CO})\text{NbCl} + \text{SnCl}_2 \rightarrow \text{Cp}_2(\text{CO})\text{NbSnCl}_3 \quad \text{(108)}
\]
\[
[XW(CO)_5]^- + SnX_2 \rightarrow [(CO)_5WSnX_3]^- \\
M = Cr, Mo, W; X = Cl, Br
\]

\[
[Cp(CO)_3MoMe] + Sn(CH(SiMe_3)_2)_2 \rightarrow [Cp(CO)_3MoSn(CH(SiMe_3)_2)_2Me]
\]

\[
CpFe(\text{diphos})Cl + SnX_2 \rightarrow Cp(\text{diphos})FeSnX_2Cl
\]

More recently, interesting Os–H–Sn and Os–H–Os bridging species, 87 and 88, were obtained from the reaction of Sn[CH(SiMe_3)_2]_2 with OsH_2(CO)_10 (equation 112)\(^{266,267}\). The insertion of SnCl_2 into the metal–metal bonds of Me_2E[\(\eta^5\)-C_5H_4M(CO)_2]_2(\(\mu\)-CO)_2 (E = Si, M = Ru; E = Ge, M = Fe, Ru) affords heteronuclear cyclic complexes 89\(^{268}\).

\[
\text{OsH}_2(CO)_{10} + SnR_2 \rightarrow \text{reflux n-pentane}
\]

6. Use of distannane and distannoxane reagents

Hexamethylditin, Me_3SnSnMe_3, with its weak Sn–Sn bond, has proven a very useful reagent to form direct transition metal–tin bonds. Selected examples are noted in equations 113, \(^{269,270}\) 114 and 115\(^{271,272}\).

\[
\text{Me}_3\text{SnSnMe}_3 + Ru_3(CO)_{12} \rightarrow (CO)_4Ru(SnMe)_3 + \text{Me}_{10}\text{Sn}_4\text{Ru}_2(CO)_6
\]

\[
\text{Me}_3\text{SnSnMe}_3 + ML_2(\text{PMe}_3) \rightarrow ML_2(SnMe)_2
\]

\[
\text{Me}_3\text{SnSnMe}_3 + Co_2(CO)_8 \rightarrow \text{Me}_3\text{SnCo}(CO)_4 + \text{Me}_2\text{Sn}[Co(CO)_4]_2
\]
Recent examples include the insertion of platinum into the Sn–Sn bond of hexamethyldistannane (equation 116) and of a distannaferrocenophane, 90 (equation 117)\(^{273,274}\).

\[
\text{Me}_3\text{SnSnMe}_3 + (\text{Ph}_3\text{P})_2\text{Pt}(\text{C}_2\text{H}_4) \rightarrow \text{Me}_3\text{SnPPh}_3 \quad \text{(116)}
\]

\[
\text{Me}_3\text{SnSnMe}_3 + (\text{Ph}_3\text{P})_2\text{Pt}(\text{C}_2\text{H}_4) \rightarrow \text{Me}_3\text{SnPPh}_3 \quad \text{(117)}
\]

Similar reactions of organolanthanide reagents, RLn (Ln = Yb, Eu, Sm), with hexaalkyl(aryl) distannanes resulted in formation of reactive organometallic derivatives with Sn–Ln bonds, R\(_3\)SnLn\(^{275,276}\).

Several examples of the use of hexamethyldistannoxane as a Me\(_3\)Sn group transfer agent are reported. Thus the dimetallic carbonyl dimers of Mo, Mn, Fe, Co, and Ni react with Me\(_3\)SnOSnMe\(_3\) [and also with tris(trimethylstannyl)amine, N(SnMe\(_3\))\(_3\)] to form metal-carbonyl derivatives containing tin complexes (equation 118)\(^{277}\).

\[
\text{Mn}_2(\text{CO})_{10} + \text{Me}_3\text{SnOSnMe}_3 \rightarrow 2(\text{CO})_5\text{MnSnMe}_3 \quad \text{(118)}
\]

The reaction depicted in equation 119 is an interesting example of an oxygen transfer from tin; the diorganotin sulfides and acetates react similarly under the same conditions (refluxing iron pentacarbonyl)\(^{278}\).

\[
2\text{Fe}(\text{CO})_5 + 2/n(\text{Bu}_2\text{SnO})_n \rightarrow [\text{Bu}_2\text{SnFe}(\text{CO})_4]_2 + 2\text{CO}_2 \quad \text{(119)}
\]

7. Organotin group transfer via Sn–C bond cleavage

As noted in several instances in the foregoing chemistry, the tin–carbon bond is often quite labile. This is particularly true for the Sn–C(sp\(^1\), sp\(^2\)) linkages and has been used to synthesize metal–tin bonds. The reactions of alkylnitin compounds with iron carbynols result in Sn–C(alkyne) bond cleavage with formation of \([\text{R}_2\text{SnFe}(\text{CO})_4]_2\) and \([\text{R}_2\text{SnFe}(\text{CO})_3(\text{PPh}_3)]_2\)^{279}. Trimethylcyclopentadienyltin, CpSnMe\(_3\), reacts with bi- and polynuclear metal carbonyls to form MSnMe\(_3\), where M = Mn(\text{CO})\(_5\), Re(\text{CO})\(_5\), Co(\text{CO})\(_4\), CpMo(\text{CO})\(_3\), CpFe(\text{CO})\(_2\), CpNi(\text{CO}) and Fe(\text{CO})\(_4\), via cleavage of the M–M bond and transfer of the SnR\(_3\) group to the metal\(^{93}\).

More recently vinyltin derivatives, H\(_2\)C=CHSnR\(_3\), were found to transfer SnR\(_3\) groups to ruthenium and osmium. Thus, high yields of R\(_3\)SnRuCl(\text{CO})(\text{PPh}_3)_2 (R = Me, Bu, p-Tol) are obtained from H\(_2\)C=CHSnR\(_3\) and RuHCl(\text{CO})(\text{PPh}_3)_3, probably via insertion of the vinylstannane into the Ru–H bond, followed by a \(\beta\)-elimination of ethylene from the \(\beta\)-stannyethyl complex formed\(^{280}\). Similarly, the osmium complex, Me\(_3\)SnOsCl(\text{CO})(\text{PPh}_3)_2, was obtained from OsHCl(\text{CO})(\text{PPh}_3)_3 and H\(_2\)C=CHSnMe\(_3\)^{281}. 
A relatively unusual cleavage of the Sn−C(sp³) bond is illustrated in equation 120\textsuperscript{282}.

\[
\text{Ru}_3(\text{CO})_{12} + \text{Me}_3\text{SnCH}_2\text{NMe}_2 \rightarrow (\text{Me}_3\text{Sn})_2\text{Ru}(\text{CO})_4 + \text{HRu}_3(\text{CO})_{10}(\text{:CNMe}_2)
\] (120)

The migration of a triphenyltin group from a carbene (CO),\textsubscript{5}Cr:C(SnPh\textsubscript{3})NE\textsubscript{t}_2, on treatment with PPh\textsubscript{3} with loss of CO, leads to a carbyne complex, \textit{trans}-[(CO)\textsubscript{4}Cr(SnPh\textsubscript{3})(:CNE\textsubscript{t}_2)]; the reaction follows a first order kinetics\textsuperscript{283,284}.

### 8. Miscellaneous reactions

Recent studies have illustrated a number of interesting synthetic pathways to metal–tin bonds. For example the metal exchange reaction involving Yb and Sm complexes leads to new rhenium–tin compounds (equation 121)\textsuperscript{285}.

\[
2\text{CpRe}(\text{CO})_2(\text{MI}) + 2\text{ClSnPh}_3 \rightarrow \text{Cp}(\text{CO})_2\text{Re}(\text{SnPh}_3)_2 + \text{CpRe}(\text{CO})_2\text{I}_2 + \text{MCl}_2 + \text{MI}_2 (\text{M} = \text{Yb}, \text{Sm})
\] (121)

The oxidative decarbonylation reaction of \text{Cp}^R\text{Ti}(\text{CO})_2(\text{R} = \text{H, Me}) with aryltin halides, e.g. \text{Cl}_2\text{SnPh}_2 and \text{XSnPh}_3 (\text{X} = \text{Cl, Br, I}), gave the insertion product \text{Cp}^R(\text{X})\text{TiSnR}_2\text{X}' (\text{X}' = \text{R, X})\textsuperscript{286}. Similarly, \text{bis}(3,5\text{-dimethylpyrazolyl})\text{ethane (bmpze)} complexes of the type \text{M}(\text{CO})_4(\text{bmpze}) (\text{M} = \text{Mo, W}) react with \text{RSnCl}_3 (\text{R} = \text{Cl or Ph}) in CH\text{Cl}_2 at room temperature to give seven-coordinate insertion products \text{[(bmpze)(CO)\textsubscript{3}(Cl)M(SnRCl\textsubscript{2})]}\textsuperscript{287}. Related nitrile complexes \text{[M(CO)\textsubscript{3}(NCR)_\textsubscript{3}]} react with organotin trichlorides \text{R'SnCl}_3 to form \text{[CO]_\textsubscript{3}M(NCR)_\textsubscript{2}(Cl)M(SnR'\textsubscript{2}Cl\textsubscript{2})]} (where \text{M} = \text{Mo, W, R = Me or Et, R' = Bu or Ph) involving elimination of the nitrile}\textsuperscript{288,289}.

An unusual insertion occurs in a reaction of a substituted bipyridyl complex of dimethylplatinum with cyclic chalcogenotin compounds to form 91 (equation 122)\textsuperscript{290}.

\text{SnR}_2
\]
The dinuclear carbonyl Fe$_2$(CO)$_9$ reacts with Ph$_2$PCH$_2$CH$_2$SnPh$_3$ to form a chelated complex 92 via (CO)$_4$FePPh$_2$CH$_2$CH$_2$SnPh$_3$; the same compound is formed in the reaction of (CO)$_4$Fe(H)SiMePh$_2$ with Ph$_2$PCH$_2$CH$_2$SnPh$_3$ via a silyl group elimination.$^{291}$

\[ \text{Ph}_2\text{Fe} \quad \text{Ph}_2\text{P} \quad \text{SnPh}_2 \quad \text{OC} \quad \text{OC} \]

(92) \hspace{1cm} (93)

In a similar manner Fe$_2$(CO)$_9$ also reacted with Ph$_2$P(CH$_2$)$_n$SnR$_2$R$^\prime$ ($n = 2$, R$' = \text{Ph}$; R$_2 = \text{Ph}_2$, MePh; R$' = \text{Me}$, R$_2 = \text{Me}_2$; $n = 1$, 3, R$_2$R$' = \text{Ph}_3$) to give (CO)$_x$Fe[Ph$_2$P(CH$_2$)$_n$SnR$_2$R$'$]$_{5-x}$ ($x = 1$, 2) which, upon UV irradiation, gave the chelated phosphinoalkyl complexes (CO)$_3$Fe[Ph$_2$P(CH$_2$)$_n$SnR$_2$] by intramolecular oxidative addition of the SnR$'$ group$^{292}$. Similar compounds, 94–96, have been recently reported for nickel and platinum chemistry involving loss of a tin–phenyl group$^{293}$.

\[ \text{R}_3\text{SnCH}_2\text{CH}_2\text{P} \quad \text{R}_2\text{P} \quad \text{SnSn} \quad \text{Ni} \quad \text{Ph}_2 \quad \text{Ph}_2 \]

(94) R = Ph, M = Ni

(95) R = Me, M = Pt

The compound Cp(CO)$_2$FeSnMe$_2$GeMe$_3$, which can be prepared directly, was also formed by photoisomerization of its isomer Cp(CO)$_2$FeGeMe$_2$SnMe$_3$, prior to photoelimination of GeMe$_2$ and SnMe$_2$, to form Cp(CO)$_2$SnMe$_3$ (40%) and Cp(CO)$_2$FeGeMe$_3$ (60%)$^{15}$. This rearrangement (equation 123) contrasts the behavior of the related SiGe isomers where only photoelimination of the germylene was observed$^{13}$.

\[ \text{Fp-GeMe}_2\text{SnMe}_3 \quad \text{Fp-SnMe}_2\text{GeMe}_3 \]

(123)
The insertion of platinum into a Sn–C bond, presumably relieves the strain of a ferrocenophane and forms the metallocycle 97 (equation 124).

\[
\begin{align*}
\text{Fe} & \quad \text{Sn(Bu-\text{t})}_2 \\
\text{Fe} & \quad \text{Pt} \quad \text{Pt} \\
\text{Sn(Bu-\text{t})}_2 & \\
\end{align*}
\]

\[\text{Pt}(1,5-\text{COD})_2\]

(124)

B. Synthesis of Stannylene Complexes

The stannynes and their transition metal complexes have been dealt with in a series of recent reviews. We concentrate upon the most recent developments which chiefly involve direct reactions of preformed stannynes with various metal complexes (equation 125). The addition of SnCp₂ or SnCp′₂ to THF solutions of M(CO)₅THF (M = Cr, Mo, W) yields stannylene complexes R₂SnM(CO)₅ (R = Cp, M = Cr, Mo; R = Cp′, M = Cr, W).  

\[
\begin{align*}
\text{M(CO)}_5\text{L} + \text{R}_2\text{Sn} & \rightarrow \text{R}_2\text{SnM(CO)}_5 \\
(M = \text{Cr, Mo, W}; \text{L} = \text{CO}; \text{R} = \text{Me, t-Bu})
\end{align*}
\]

(125)

This is a very general procedure and a variety of stannynes have been used to form donor-free complexes, Sn[CH(SiMe₃)₂]₂; alkylarylstitannylene SnRR′(R = 2, 4, 6-(t-Bu)₃C₆H₂, R′ = CH₂CMe₂-C₆H₃(Bu-t)₂-3, 5); SnCp₂ and SnCp′₂. In the latter case the pentahapto bonding of the cyclopentadienyl rings to tin is retained. The Mössbauer spectra demonstrate a synergic tin–metal σ and metal–tin π bonding along the tin–metal axis.

The reaction of Cp₄Co(η²-C₂H₄)₂ (R = H, Me) with Sn[CH(SiMe₃)₂]₂ leads to the formation of a stannylene complex, 98 (equation 126).

\[
\begin{align*}
\text{Co} & \quad \text{Sn} \\
\text{CH(SiMe₃)₂} & \quad \text{CH(SiMe₃)₂} \\
\end{align*}
\]

(98)

Although cationic stannylene manganese complexes are well established, e.g. Me₂Sn=Mn(CO)₅⁺BF₄⁻, only recently was it shown that treatment of Mn₂(CO)₁₀ with SnRR′(R = 2, 4, 6-(t-Bu)₃C₆H₂; R′ = CH₂CMe₂(C₆H₃(Bu-t)₂-3, 5) provides a tetracarbonylstannylene complex 99 containing a heterocyclic moiety formed in the
process of cyclometallation (equation 127).\(^{303}\)

\[
\text{Mn}_2(\text{CO})_{10} + \text{SnRR}' \rightarrow \text{R'OC CO} \quad \text{Sn} \quad \text{R} \quad \text{Mn} \quad \text{Sn} \quad \text{OC CO} \\
\text{Bu-t} \quad \text{Bu-t} \quad \text{Me} \quad \text{Me} \quad \text{t-Bu} \quad \text{t-Bu} \\
(99) \quad \text{(127)}
\]

The reaction of Sn(\(\eta^1\text{-Cp})_2\) with diiron enneacarbonyl produces bridging stannylene complexes (equation 128).\(^{298,304,305}\)

\[
\text{Sn}(\eta^1\text{-Cp})_2 + \text{Fe}_2(\text{CO})_9 \rightarrow [(\eta^1\text{-Cp})_2\text{SnFe(\text{CO})}_4]_2 + \text{CO} \quad (128)
\]

Similarly, Sn(C\(_5\)Me\(_5\))\(_2\) and CpSnX (X = Cl, Br) react with Fe\(_2\)(CO)\(_9\) in benzene to give cyclic dimers [Cp\(^2\)*SnFe(CO)\(_4\)]\(_2\) and [CpXSnFe(CO)\(_4\)]\(_2\), respectively.\(^{306}\) The homolytic cleavage of these dimers, with even relatively weak Lewis bases, produce base-stabilized stannylene complexes of the type (CO)\(_4\)FeSnR\(_2\).\(^{298,306}\) The relative cleavage propensity for metals is: Ge > Sn > Pb and for bases is: Py > acetone > THF > Et\(_2\)O.\(^{307}\)

A rare metal atom synthesis was used for the preparation of \((R_2\text{Sn})_2\text{Fe}(\eta^6\text{-toluene})\), \(R = 2\text{-}(t\text{-Bu})-3,4,5\text{-Me}_3\text{C}_6\text{H}\), from Fe atoms, toluene and the stannylene SnR\(_2\).\(^{308}\) and for the synthesis of \((R_2\text{Sn})\text{Fe}(\mu^2\text{-C}_2\text{H}_4)(\eta^6\text{-toluene})\) where \(R = 2\text{-}(t\text{-Bu})-4,5,6\text{-Me}_3\text{C}_6\text{H}\) or CH(SiMe\(_3\))\(_2\). The latter reacts with CO at \(-20^\circ\text{C}\) in toluene to form \(R_2\text{SnFe}(\text{CO})_4\) and \((R_2\text{Sn})_2\text{Fe}(\text{CO})_3\). A metal atom route, involving solvated nickel atoms, was used to prepare red to purple, crystalline stannylene complexes of the type Ni(SnR\(_2\))\(_4\), with \(R = \text{CH(SiMe}_3)\(_2\)\) and C\(_6\)H(Bu-t)\(_2\)Me\(_3\)-4,5,6 at \(-78^\circ\text{C}\) in 58 and 33% yields, respectively.\(^{310}\)

The stannylene Sn[CH(SiMe\(_3\))\(_2\)] behaves as a Lewis base in its reactions with [CpFe(CO)\(_2\)]\(_2\) to form Cp\(_2\)Fe(CO)\(_3\)(SnR\(_2\)). Pyridine, 4-methylpyridine and piperidine form dissociable 1 : 1 adducts.\(^{265}\)

On the other hand, the mixed nitrile/carbonyl complexes of the three metals all react; \([\text{Fe}_3(\text{CO})_{11}\text{MeCN}] \rightarrow [\text{Fe}_2(\text{CO})_6(\mu\text{-SnR}_2)_2]\); \([\text{Ru}_3(\text{CO})_{10}\text{MeCN}] \rightarrow [\text{Ru}_3(\text{CO})_{10}(\mu\text{-SnR}_2)_2]\); \([\text{Os}_3(\text{CO})_{10}\text{MeCN}] \rightarrow [\text{Os}_3(\text{CO})_{10}(\mu\text{-SnR}_2)_2]\).\(^{311}\)

Treatment of Cp(\(\text{CO}\))(SnMe\(_3\))Fe{PN(Me)CH\(_2\)CH\(_2\)NM(e OR)}\(_2\)(R = Me, Et) with Me\(_3\)SiOSO\(_2\)CF\(_3\) resulted in P–OR bond cleavage and migration of a methyl group from tin to phosphorus, to yield an unusual stannylene complex.\(^{100,312}\)
Cyclic diazastannynes, Sn(NBu-t)₂SiMe₂, afford a series of interesting stannylene complexes. They insert into the Fe–Me bond of Cp(CO)₂FeMe, to form the corresponding stannylene complex 101.

A reaction of the four-membered cyclic stannylene with nickelocene gave compound 102 with a Sn–Ni–Sn fragment.

With NiBr₂, PdCl₂ and PtCl₂ the cyclic diazastannylene, Sn(NBu-t)₂SiMe₂ form compounds containing four Sn–M bonds, 103, but with MX₂ (M = Cr, Fe, Co, Zn; X = Cl, Br) the compounds formed are totally different and do not contain M–Sn bonds.

More sophisticated structures 104 and 105 are obtained by reactions of the cyclic diazastannylene, Sn(NBu-t)₂SiMe₂ with [(CO)₃Fe(μ-CO)(μ-Ph₂PXPh₂)Pt(PR₃)] (X = CH₂ or NH) and mer-[(CO)₂Fe{μ-Si(OMe)₂(OMe)}(μ-dppm)M(Me)] (M = Pd, Pt), respectively.

The stannylene Sn[CH(SiMe₃)₂]₂ reacts with [Os₃(CO)₈(μ-H)(μ-C₆H₄PhCH₂CH₂PPh₂)] and reverses the orthometallation used for its formation, to afford [Os₃(SnR₂)₂(μ-dppm)(CO)₈].
The ethylene complex \( \text{Cp}^\ast\text{Co}(\eta^2-\text{C}_2\text{H}_4)_2 \) reacts with the stannylene \( \text{SnR}_2 \), \( R = 6-t\text{-Bu-2,3,4-Me}_3\text{C}_6\text{H} \), to form \( \text{Cp}^\ast(\eta^2-\text{C}_2\text{H}_4)\text{CoSnR}_2 \), 106, which can be converted to the trinuclear \( \text{bis[bis}[6\text{-}t\text{-} \text{Bu-2,3,4\text{-}trimethylphenyl}]]\text{stannio} (\eta^5\text{-pentamethylcyclopentadienyl})\text{-cobalt(I)} \) 107 \( (\text{R}_2\text{Sn})_2\text{CoCp}^\ast \) upon heating 316.

The stannylene \( \text{SnR}_2 \) with \( R = \text{CH}\left(\text{SiMe}_3\right)_2 \) reacts with \( \text{RhCl(PPh}_3)_3 \) to form the addition product \( \text{R}_2\text{SnRhCl(PPh}_3)_2 \) 2265.

The stannylene \( \text{Sn}[\text{CH}\left(\text{SiMe}_3\right)_2]_2 \) reacts with \( \text{Ni(C}_2\text{H}_4)_3 \) and affords \( (\text{C}_2\text{H}_4)_2\text{NiSn}[\text{CH}(\text{SiMe}_3)_2]_2 \)-L with \( L = \text{NH}_3, \text{pyridine}, \text{OP(NMe}_2)_3 \), could be obtained 317. The ethene ligand can be displaced by CO to form \( \text{(CO)}_3\text{NiSn}[\text{CH(\text{SiMe}_3)_2}]_2 \), from which adducts \( \text{(CO)}_3\text{NiSn}[\text{CH(\text{SiMe}_3)_2}]_2 \)-L can also be prepared 317.

With toluene solvated nickel atoms, the stannylenes \( \text{Sn}[\text{CH(\text{SiMe}_3)_2}]_2 \) and \( \text{Sn(\text{C}_6\text{H}-2-t\text{-Bu-3, 4, 5-Me}_3)_2} \) at \(-78^\circ \text{C} \) form homoleptic stannylene analogs of nickel tetracarbonyl, \( \text{Ni(SnR}_2)_4 \) with \( R = \text{CH(\text{SiMe}_3)_2} \) and \( 2,3,4\text{-Me}_3-6-t\text{-BuC}_6\text{H}_3 \). The four membered cyclic stannylene \( \text{Sn(NBu-t}_2)\text{SiMe}_2 \) can also form a similar homoleptic complex 319.
The dimer \([\text{CpNi(PEt}_3])_2\) adds the stannylene \(\text{Sn}[\text{CH(SiMe}_3]_2]\) and eliminates the tri-ethylphosphine to form tetranuclear \([\text{CpNiSn}[\text{CH(SiMe}_3]_2]\) with a butterfly molecular structure which preserves the Ni–Ni bond. Alternatively, the same compound can be obtained directly from nickelocene and \(\text{Sn}[\text{CH(SiMe}_3]_2\) in 83% yield. The acetylene diphosphine chelate complex \(\text{Ni}(\text{HC}≡\text{CH})(\text{i-Pr})_2\text{PCH}_2\text{CH}_2\text{P(Pr-)}_2\) reacts with the stannylene \(\text{Sn}[\text{CH(SiMe}_3]_2\) (below \(-30^\circ\text{C}\)) in a different manner, by forming a stanna(I)nickela(II)cyclobutene complex (equation 131) which dissociates reversibly (up to \(20^\circ\text{C}\)) in solution to the starting components.

\[
\begin{align*}
\text{Ni} & \quad \text{P} \quad \text{P} \quad \text{Ni} \\
i-\text{Pr} & \quad \text{Pr-}i \quad \text{H} \quad \text{H} \\
i-\text{Pr} & \quad \text{Pr-}i
\end{align*}
\]

The four-membered cyclic stannylene \(\text{Sn(NBu}_-t)_2\text{SiMe}_2\) reacts with nickelocene to give an 87% yield of insertion product containing a CpNi moiety bridging two tin atoms. The structure was established by single crystal X-ray diffraction.
Tin(II) chloride behaves as a stannylene by inserting into the Ni–Ni bond of \([\text{CpNi(PEt}_3\text{)}]_2\) to form 108, in which both chlorine atoms can be replaced by alkyl groups in reactions with LiR (R = Me, Bu)\(^{322}\).

![Image of 108](image)

The reaction of \((\text{CO})_5\text{MnSnMe}_3\) with BF\(_3\) gives the stannylene complex \([\text{Me}_2\text{Sn:Mn(\text{CO})}_5]\text{BF}_4\); the same compound can be obtained from \((\text{CO})_5\text{MnSnMe}_2\text{Cl}\) with AgBF\(_4\) (equation 132)\(^{302}\).

\[
\begin{align*}
\text{(CO)}_5\text{MnSnMe}_3 + \text{BF}_3 & \rightarrow [\text{Me}_2\text{Sn:Mn(\text{CO})}_5]\text{BF}_4 \\
\text{(CO)}_5\text{MnSnMe}_2\text{Cl} + \text{AgBF}_4 & \rightarrow [\text{Me}_2\text{Sn:Mn(\text{CO})}_5]\text{BF}_4
\end{align*}
\]

\(\text{(132)}\)

C. The Reactivity of the Transition Metal Tin Single Bond

1. Thermal stability

There are widespread reports concerning the thermal stability of various M–Sn bonds; however, no systematic studies are apparent involving the effect on this stability of the metal component. A common decomposition pathway of triorganotin complexes involves the formation of ditin compounds as noted below for V and Hg complexes (equations 133\(^{323}\) and 134\(^{241,324}\)).

\[
\begin{align*}
2\text{Cp}_2\text{VSnEt}_3 & \rightarrow \text{Et}_3\text{SnSnEt}_3 + 2\text{Cp}_2\text{V} \\
\text{Hg}(\text{SnR}_3)_2 & \rightarrow \text{Hg} + \text{R}_3\text{SnSnR}_3
\end{align*}
\]

\(\text{(133)}\) \quad \text{(134)}

(R = Me, Et, Pr, Bu, Ph)

A study of the chemistry in equation 134 showed that the bulkier the R group, the more stable the complex, a typical feature of bulky ligands increasing the kinetic stability of many transition-metal and main group element complexes. The related thermal decomposition of alkyl(trimethyltin)mercury complexes, RHgSnMe\(_3\) (R = Me, Et, Pr, i-Pr, t-Bu), was investigated using CIDNP techniques and showed that the mechanism, not surprisingly, involved the formation of free radicals\(^{325,326}\). The very bulky arrangement of bis(tris-trimethylsilylmethyltin) mercury results in a distinctive decomposition route, presumably due to the instability of the related ditin compound (equation 135)\(^{327}\).

\[
\text{Hg}[\text{Sn(CH}_2\text{SiMe}_3)_3\text{]}_2 \rightarrow \text{Sn(CH}_2\text{SiMe}_3)_4 + \text{Hg}
\]

\(\text{(135)}\)

Solutions of \([\text{Zr(\text{CO})}_5(\text{SnMe}_3)_2]\)\(^{-2}\) in acetonitrile decompose within hours at 20\(^{\circ}\)C, to give the more stable anion \([\text{Zr(\text{CO})}_4(\text{SnMe}_3)_4]\)\(^{-2}\) containing eight-coordinate zirconium\(^{328}\).
A limited number of thermal redistribution reactions are reported, involving redistribution at both the tin and metal centers of the Sn–M complex (equations 136 and 137). The product in equation 137 contains a cyclic Os₃Sn₃ skeleton. A similar multimetal product 109 was obtained by the pyrolysis of the stannylene complex \([\eta^1\text{Cp}_2\text{SnFe(}CO\text{)}_4]_2\).

\[
\begin{align*}
2 \quad \text{Mo} & \quad \text{SnMe}_3 \\
\text{L} & \quad \text{CO} \quad \text{CO} \\
\text{L} & \quad \text{CO} \quad \text{CO} \\
\text{L} & \quad \text{CO} \quad \text{CO} \\
\end{align*}
\]

\[\text{(L = PPh}_3\text{)}\]

\[3 \ [\text{Me}_2\text{SnOs(}CO\text{)}_4]_2 \longrightarrow 2 \ [\text{Me}_2\text{SnOs(}CO\text{)}_3]_3\]  

(137)

2. Photostability

The limited data on the photostability of metal–tin complexes suggest that a process similar to that occurring in the thermal decompositions can take place. For example, RHgSnMe₃ (R = Me, Et, Pr, i-Pr, t-Bu) complexes produce ditin compounds via a radical process and Hg(SnR₃)₂ (R = Me, Et, Bu, Ph, CH₂C(Bu-t)₃, t-Bu) exhibit a stability proportional to the bulk of the organic radical substituent.

Interestingly, irradiation of \([\text{Me}_2\text{SnOs(}CO\text{)}_4]_2\) produced a different cluster compound than that obtained thermally in equation 137, i.e. 110 (equation 138).

\[
\begin{align*}
\text{Fe(}CO\text{)}_2\text{Cp} & \\
\text{(}CO\text{)}_3\text{Fe} & \quad \text{Sn} \\
\text{(}CO\text{)}_3\text{Fe} & \quad \text{Sn} \\
\text{Fe(}CO\text{)}_2\text{Cp} & \\
\end{align*}
\]

(109)

\[\text{hv} \quad [\text{Me}_2\text{SnOs(}CO\text{)}_4]_2 \longrightarrow (\text{Me}_2\text{Sn})_4\text{Os}_4(}CO\text{)_14\]  

(110)

The new cluster compound contains a planar Os₄Sn₄ skeleton consisting of a central rhomboidal Os₂Sn₂ unit fused to two outer Os₂Sn triangles.

Photolysis of Me₂Sn[Mn(CO)₅]₂ proceeds with loss of carbon monoxide and four-membered ring closure to form 111, and similar bridging stannylene complexes 112 and 113 are formed by the photochemical treatment of related Fe and Co complexes.

Photolysis of \([\text{(L)}_2(}CO\text{)_3\text{MnSnR}_3\text{]}\), R = Me, Et, L = P(OPh)₃, resulted in loss of the stannyl group and formation of an orthometallation product 114 involving the phosphite
3. Insertion reactions

A variety of simple insertion reactions are reported for the M–Sn bond, involving species as disparate as Te\textsuperscript{239}, CS\textsubscript{2}\textsuperscript{2337}, SO\textsubscript{2}\textsuperscript{203,338}, dienes and acetylenes (equations 140–143).

\[
\text{Cp}_2^+\text{Ti}–\text{SnPh}_3 + \text{Te} \rightarrow \text{Cp}_2^+\text{Ti}–\text{Te}–\text{SnPh}_3 \quad (140)
\]

\[
\text{(triphos)CuSnMe}_3 + \text{CS}_2 \rightarrow \text{(triphos)CuS}_2\text{CSnMe}_3·\text{CS}_2 \quad (141)
\]

\[
[(\text{CO})_5\text{WSnMe}_3]^- + \text{SO}_2 \rightarrow [(\text{CO})_5\text{WS(O)SnMe}_3]^- \quad (142)
\]

\[
\text{Cp}(\text{CO})_2(\text{PPh}_3)\text{MoSnR}_3 + \text{SO}_2 \rightarrow \text{Cp}(\text{CO})_2(\text{PPh}_3)\text{MoOS(O)SnR}_3 \quad (143)
\]

\[(R = \text{Me, Ph})\]

The insertion chemistry noted in equation 141 relies upon the steric bulk imparted by the phosphine ligand. The related nonphosphine-containing complexes, Cp(\text{CO})_3\text{MSnPh}_3 (M = \text{Mo, W}), react with liquid sulfur dioxide to give dimersion products formulated as Cp(\text{CO})_3\text{MSnPh}_3·\text{SO}_2, in which insertion takes place into both the M–Sn and C–Sn bonds. Similarly, depending upon the temperature, the methyl analogs \text{Cp}(\text{CO})_3\text{MSnMe}_3 insert either one or two moles of SO\textsubscript{2}. The related bimetals, Ph\textsubscript{2}Sn[M(\text{CO})_5\text{Cp}_2], more bulky materials, do not react with SO\textsubscript{2}; however, the tungsten salt [(\text{CO})_5\text{WSnMe}_3]^- reacts at ambient temperature to form the mono-insertion product [(\text{CO})_5\text{WS(O)SnMe}_3]^-\textsuperscript{203,338}.

Reactions of (\text{CO})_5\text{MnSnR}_3 (M = \text{Mn, R = Me, Ph; M = Re, R = Me}) with liquid sulfur dioxide resulted in the formation of various products with insertions into the Sn–C bonds as well as the Sn–M bond\textsuperscript{339,340}. This type of chemistry exemplifies the relatively reactive nature of the Sn–C bond compared to the metal–Sn bond, \textit{vide supra}. In (\text{CO})_5\text{MnSnMe}_3 only the Mn–Sn bond reacts, but (\text{CO})_5\text{ReSnMe}_3 undergoes insertion into one Sn–C bond; Ph\textsubscript{2}Sn[Mn(\text{CO})_5]_2 incorporates three equivalents of SO\textsubscript{2} inserting into the Mn–Sn bond and two Sn–C bonds, whereas under the same conditions the
methyl analog, \( \text{Me}_2\text{Sn}[\text{Mn}(\text{CO})_5]_2 \), decomposes. In the case of iron complexes, insertion occurs only into the Sn–C bond (equation 144)\(^{341a}\).

\[
\text{CpFe(CO)}_2\text{SnPh}_3 + 2\text{SO}_2 \rightarrow \text{CpFe(CO)}_2\text{SnPh[OS(O)Ph]}_2
\] (144)

Fluoroalkenes and fluoroalkynes, e.g. perfluoropropene, perfluoro-2-butyne and perfluorocyclobutene, insert into M–Sn bonds, M = Mn, Fe (equation 145)\(^{341b}\).

\[
\text{Me}_3\text{SnMn(CO)}_5 + \text{CF}_3\text{C≡CCF}_3 \rightarrow \text{Me}_3\text{Sn(CF}_3\text{)}_2\text{C} = \text{C(CF}_3\text{)}\text{Mn(CO)}_5
\] (145)

Similar chemistry occurs with \( \text{R}_3\text{SnCo(CO)}_4 \) if the reaction is performed photochemically in hexane; however, when conducted thermally in polar solvents, cobalt fluorides, \( \text{R}_3\text{SnF} \) and cobalt cluster compounds are formed\(^{342}\). In the case of an attempted insertion into a Rh–Sn bond under photochemical conditions, ligand exchange chemistry occurred (equation 146)\(^{343}\).

\[
\text{F}_2\text{C} = \text{CF}_2 + \text{Me}_3\text{SnRh(CO)}_2(\text{PPh}_3)_2 \rightarrow \text{Rh(CF} = \text{CF}_2)(\text{CO})_2(\text{PPh}_3)_2 + \text{FSnMe}_3
\] (146)

Attempted insertions of fluorocarbenes into Sn–Mn and Sn–Fe bonds were unsuccessful; thus, the thermal reaction of \( (\text{CO})_3\text{MnSnMe}_3 \) with \( \text{Me}_3\text{SnCF}_3 \) (a good source of carbene \( \text{CF}_2 \)) led instead to a disproportionation reaction involving formation of \( (\text{CO})_3\text{MnSnMe}_2(\text{CF}_3) \) and \( \text{SnMe}_4 \)\(^{344}\).

A very high yield insertion of a reactive, coordinatively unsaturated, metallic species into the Hg–Sn bond has been reported (equation 147)\(^{345,346}\).

\[
\text{Hg}[\text{Sn(C}_6\text{F}_5)_3]_2 + \text{M}(\text{PPh}_3)_2 \rightarrow (\text{C}_6\text{F}_5)_3\text{SnHgM(PPh}_3)_2\text{Sn(}C_6\text{F}_5)_3
\] (M = Pd, Pt) (147)

Similarly, from a mixed germyl(stannyl)mercury compound, the tetrametallic complex \( (\text{C}_6\text{F}_5)_3\text{SnHgM(PPh}_3)_2\text{Ge(}C_6\text{F}_5)_3 \) was obtained as a mixture of cis and trans isomers\(^{345}\).

4. Metal tin bond cleavage

The metal–tin bond is readily cleaved by a variety of reagents, e.g. \( \text{I}_2 \), \( \text{HgX}_2 \) (\( \text{X} = \text{Cl}, \text{OCOCF}_3 \)), \( \text{ClSiR}_3 \), \( \text{SiCl}_4 \), \( \text{SnCl}_4 \), \( \text{TiCl}_4 \). For example, upon treatment with either \( \text{I}_2 \) or \( \text{HgX}_2 \), the tin complexes \( \text{Cp(CO)}_3\text{MnSnR}_3 \) (\( \text{M} = \text{Cr}, \text{Mo}, \text{W}; \text{R} = \text{Me}, \text{Bu}, \text{Ph} \)) form the corresponding \( \text{Cp(CO)}_3\text{MI(HgX)} \) and \( \text{R}_3\text{SnX} \) compounds. Both processes involve charge transfer or adduct intermediates and although cleavage by iodine is accompanied by some CO evolution, this is not the case for the cleavage by \( \text{HgX}_2 \)\(^{347−352}\). Treatment of the same tin complexes with organomercury halides, \( \text{RHgCl} \) (\( \text{R} = \text{Me}, \text{Ph}, \text{allyl} \)), in acetone results in the initial formation of \( \text{Cp(CO)}_3\text{MHgR} \) followed by symmetrization (\( \text{M} = \text{Mo}, \text{W} \)) (equations 148 and 149)\(^{250}\).

\[
\text{Cp(CO)}_3\text{MnSnMe}_3 + \text{RHgCl} \rightarrow \text{Cp(CO)}_3\text{MHgR} + \text{ClSnMe}_3
\] (148)

\[
2 \text{Cp(CO)}_3\text{MHgR} \rightarrow \text{HgR}_2 + \text{Hg}[\text{M(CO)}_3\text{Cp}]_2
\] (149)

The reactions between \( \text{I}_2 \), \( \text{Br}_2 \), \( \text{ICl}, \text{IBr} \) and \( (\text{CO})_5\text{MnSnMe}_3 \), \( \text{Cp(CO)}_3\text{WSnMe}_3 \), \( \text{Me}_3\text{SnRe(}CO)_5 \) and \( \text{Cp(CO)}_3\text{FeSnMe}_3 \) have been studied as have been the reactions with \( \text{RMe}_2\text{SnMn(CO)}_5 \) [\( \text{R} = \text{CpMo(CO)}, \text{CpFe(CO)}_2, \text{Co(CO)}_4 \)]\(^{349,353−360}\). The following reactivity sequence for bond cleavage was observed with iodine:

\[
\text{Sn–Co} \sim \text{Sn–Fe} > \text{Sn–Mo} \sim \text{Sn–W} > \text{Sn–Mn}
\]
Phosphonium ylides, $R_3P-CHR'$ ($R = H, Et, Bu; R' = H, Me, SiMe_3$)$^{361}$, and phosphorus halides also cleave the Mo–Sn, Fe–Sn and Co–Sn bonds$^{362}$. (equation 150 and 151).

$$\text{Cp(CO)}_n\text{MSnMe}_3 + R_3PCHR' \longrightarrow [R'\text{CH_2R}_3\text{P}]^+[\text{CpM(CO)}_n]^– + R_3\text{PCR'SnMe}_3$$

$$\text{(M = Mo, n = 3; M = Fe, n = 2)}$$

$$2\text{Me}_3\text{SnCo(CO)}_4 + 2\text{Ph}_2\text{PCl} \longrightarrow (\text{CO})_3\text{Co(μ-PPh}_2)_2\text{Co(CO)}_3 + 2\text{Me}_3\text{SnCl}$$

The analogous reaction to equation 151, using $R_2\text{AsX}$, $R = \text{CF}_3, \text{CH}_3; X = \text{Cl}, \text{I}$, gave $\text{Me}_2\text{SnX}$ and a variety of different arsenic metallic products, e.g. $[\text{Me}_2\text{AsCo(CO)}_3]_n$ and $(\text{CF}_3)_2\text{AsCo(CO)}_4$.$^{362,363}$

Mercury–tin bonds are readily cleaved by the halogenos to yield haloorganotins. The bulky complex $\text{Hg}[\text{Sn(CH(Bu-t))}_3]_2$ reacts with $\text{HgCl}_2$, iodine and $\text{Hg(CH}_2\text{COOMe})_2$ to give the respective tin-chloride (90% yield), -iodide (74% yield) and -methyl acetate (88% yield)$^{364}$.

Both cadmium and mercury compounds $M[\text{SnR}_3]_2$ ($R = \text{Me, Et, Pr, t-Bu, Ph}$) are oxidized by air to the related stannoxanes and $\text{MO}$ ($M = \text{Cd}$) or $M$ ($M = \text{Hg}$)$^{239,241}$. Peroxides, e.g. $\text{Bz}_2\text{O}_2$, also perform similar oxidations to form $\text{M(OBz)}_2(M = \text{Cd})$ and $\text{BzOSnR}_3$$^{365}$. Even the thermally stable complexes with bulky ligands ($R = \text{Me}_3\text{SiCH}_2$) are also oxidized$^{333}$.

In an interesting report, 1,2-dibromocyclohexane cleaves the $\text{Hg–Sn}$ bond in $\text{Hg}[\text{Sn(CH}_2\text{(Bu-t))}_3]$ to form $\text{Hg}$, $\text{BrSn(CH}_2\text{(Bu-t))}_3$ and cyclohexene$^{333}$. Also noteworthy is the formation of carbene complexes ($η^6$-arene)$\text{(CO)}_2\text{Cr:CrF}_2$ formed in the substitution/elimination reactions of stannyl complexes $K[(η^6$-arene)$\text{(CO)}_2\text{CrSnPh}_3]$ with activated $C$–$X$ bond in organic dihalogeno derivatives $\text{R}_2\text{CX}_2$ or ionic halides $[\text{R}_2\text{CX}]_2\text{Y}$$^{366}$.

There are reports of nominal two-electron donors cleaving the metal–tin bond. Thus, methyl cyanide displaces a $\text{SnPh}_3$ group from $[\text{NEt}_4]_2[(\text{CO})_4\text{M(SnPh}_3)_2]$ to give the complex $[\text{NEt}_4][(\text{CO})_2\text{M(SnPh}_3)_2][\text{MeCN}]$, and $\text{PPh}_3$ in turn replaces the methyl cyanide ligand to form $[\text{NEt}_4][(\text{CO})_4\text{M(SnPh}_3)_2][\text{PPh}_3]$.$^{367}$ Loss of a triphenyltin group also occurs on treating seven-coordinate $[(\text{CO})_4\text{Cr(SnPh}_3)_3]$– with $\text{LiSnPh}_3$, $\text{LiMe}$, $\text{PPh}_3$ and $(\text{Me}_2\text{N})_3\text{PO}$, with formation of the six-co-ordinate $[(\text{CO})_4\text{Cr(SnPh}_3)_2]_2$$^{2,367}$.

The metal–tin bond is readily cleaved by alkali metals to form the anionic salts of both the transition-metal and tin moieties. The complex $[(\text{dppe})\text{(CO)}_4\text{VSnPh}_3]$ is reduced by sodium metal in THF to give, after treatment with $[\text{Et}_4\text{N}]\text{Cl}$, the salt $[\text{Et}_4\text{N}][(\text{V(CO)}_4(\text{dppe})]$ and $\text{Ph}_3\text{SnSnPh}_3$, and $[(\text{triphos})\text{(CO)}_4\text{VSnPh}_3]$ is reduced to $\text{Na}[\text{V(CO)}_4(\text{triphos})].$$^{358}$ Similarly, $[(\text{PPh}_3)(\text{CO})_5\text{VSnPh}_3]$, $[(\text{dppe})(\text{CO})_4\text{NbSnPh}_3]$ and $[(\text{PPh}_3)(\text{CO})_5\text{TaSnPh}_3]$ were also reduced by sodium in THF but the products were not isolated$^{368}$.

The reduction of seven-coordinate $[\text{Et}_4\text{N}][(\text{CO})_5\text{V(SnPh}_3)_2]$ produced the six-coordinate dinegative anion $[(\text{CO})_5\text{VSnPh}_3]^–$$^{2,369}$. Many similar reductions are reported, including those of $\text{Cd}[\text{Sn(CH}_2\text{SiMe}_3)_3]_2$ and $\text{Hg}[\text{Sn(CH}_2\text{SiMe}_3)_3]_2$ by $\text{Li}$ in THF to form the tin anionic species$^{370}$.

5. Chemistry at tin

As noted above, the insertion of $\text{SO}_2$ in metal–tin complexes can occur into both the $\text{M–Sn}$ and $\text{C–Sn}$ bonds. This speaks to the reactivity of the $\text{C–Sn}$ bond in metal
complexes and indeed many reagents illustrate the robust nature of the metal–tin bond at the expense of the C–Sn bond. Thus, various acids will selectively react to cleave the tin–carbon bond (equations 152–154).

\[
\text{Cp}_2(\text{CO})\text{NbSnEt}_3 + 3\text{HCl} \rightarrow \text{Cp}_2(\text{CO})\text{NbSnCl}_3 + 3\text{C}_2\text{H}_6 \quad (152)
\]

\[
\text{Ph}_2\text{Sn}[\text{Mn(OCO)}_5]_2 + 2\text{AcOH} \rightarrow (\text{AcO})_2\text{Sn}[\text{Mn(OCO)}_5]_2 + 2\text{PhH} \quad (153)
\]

\[
\text{Ph}_2\text{Sn}[\text{Mn(OCO)}_4(\text{CNR})]_2 + 2\text{HCl} \rightarrow \text{Cl}_2\text{Sn}[\text{Mn(OCO)}_4(\text{CNR})]_2 + 2\text{PhH} \quad (154)
\]

\(R = \text{Me}, \text{Et}\)

As a further illustration of this chemistry, the complexes \(\text{Cp}'(\text{CO})_3\text{MnSnPh}_3\) and \(\text{Cp}(\text{CO})_3\text{MnSnPh}_2\text{X} (M = \text{Mo, W}; X = \text{Cl, Br})\) react with HCl or HBr to yield trihalogenotin derivatives. There are even examples of the cleavage of Sn–C bonds preferentially to the M–Sn bond by iodine (equation 155).

\[
(\text{CO})_5\text{MnSn(allyl)}_3 + 3\text{I}_2 \rightarrow (\text{CO})_5\text{MnSnI}_3 + 3\text{CH}_2=\text{CHCH}_2\text{I} \quad (155)
\]

Tin–carbon bonds in \([(\text{CO})_5\text{MnSnMe}_3]\) are cleaved by LiAlH\(_4\) or NaBH\(_4\) to form hydrides and the reaction of CF\(_3\)COCl and HSiCl\(_3\) with the same compound results in the formation of \([(\text{CO})_5\text{MnSnMe}_2\text{Cl}\)]\(_3\) (equations 156–159).

\[
[\text{Cp}_2(\text{H})\text{Nb}(\text{SnMe}_3)_2] + \text{Cl}_2\text{SnMe}_2 \rightarrow [\text{Cp}_2(\text{H})\text{Nb}(\text{SnMe}_2\text{Cl})_2] + \text{Me}_3\text{SnCl} \quad (156)
\]

\[
[(\text{CO})_5\text{WSnPh}_3]^- + [(\text{CO})_5\text{WSnCl}_3]^- \rightarrow [(\text{CO})_5\text{WSnPh}_3-n\text{Cl}_n]^- \quad (n = 1, 2, 3) \quad (157)
\]

\[
[\text{Cp}(\text{CO})_2\text{Fe}]_2\text{SnCl}_2 + [\text{Cp}(\text{CO})_2\text{Fe}]_2\text{SnPh}_2 \rightarrow [\text{Cp}(\text{CO})_2\text{Fe}]_2\text{SnPhCl} \quad (158)
\]

\[
\text{Hg}(\text{SnPh}_3)_2 + \text{RHgCl} \rightarrow \text{RHgSnPh}_3 + \text{ClSnPh}_3 \quad (159)
\]

\(R = \text{Me}, \text{Et}, \text{Ph}\)

A redistribution reaction between the Me\(_3\)Sn and I\(_2\)MeSn osmium complexes yields IMe\(_2\)SnOs(η\(^2\)–SnCNEt\(_2\))\((\text{CO})\)(PPh\(_3\))\(_2\) and further derivatization of the organotin halides is possible with a variety of reagents (pyridinium tribromide, catechol, potassium hydroxide, triethanolamine, nitrilotriacetic acid) to give the corresponding substitution compounds. The compound Hg[Sn(CH\(_2\)Bu-t\(_3\))]\(_2\) reacts reversibly with Hg(GeEt\(_3\))\(_2\) to form Et\(_3\)GeHgSn(CH\(_2\)Bu-t\(_3\))\(_3\) (equations 156–159).

A redistribution reaction between the metal–tin complexes not only provide extremely useful transition-metal-substituted organotin chlorides, but also demonstrate the chemical robustness of the M–Sn bonds. For example, whereas the W–Sn bond in \([(\text{CO})_5\text{WSnPh}_3]^-\) resists attack by dry HCl, the silicon and germanium analogs are cleaved to \([\text{ClW(OCO)}_5]-\) (49). An interesting reaction is the I\(_2\) cleavage of one Sn–Me bond in Me\(_3\)SnRuCl(\(p\)-tolyl) to give \((\text{ClMe}_2\text{Sn})\text{Ru}(\text{I})(\text{CO})(\text{CNR})(\text{PPh}_3)_2\). The final product involves the migration of chlorine from ruthenium to tin. Treatment of this chloro derivative with aqueous KOH affords a rare transition-metal hydroxo-tin derivative, \((\text{HOMe}_2\text{Sn})\text{Ru}(\text{I})(\text{CO})(\text{CNR})(\text{PPh}_3)_2\), which in turn reacts with \(\text{H}_2\text{S}\) to form \((\text{HSMe}_2\text{Sn})\text{Ru}(\text{I})(\text{CO})(\text{CNR})(\text{PPh}_3)_2\) (254).

It is apparent from the above example that, once formed, the various Sn–halogen bonds in transition-metal stannanes are subject to the normal substitution chemistry of such
17. Transition metal complexes of germanium, tin and lead

species. Typical transformations are outlined in equations 160, 161 and 162.

\[
\begin{align*}
((\text{CO})_5\text{MnSnPh})_{n-1} \text{Cl}_3^{-} + \text{LiC}_6\text{F}_5 & \rightarrow ((\text{CO})_5\text{MnSnPh})_{n-1}(\text{C}_6\text{F}_5)_3^{-} \quad (160) \\
((\text{CO})_5\text{M}_2\text{SnCl}_2 + i-\text{Bu}_2\text{AlH} & \rightarrow ((\text{CO})_5\text{M}_2\text{SnH}_2 \quad (161) \\
\text{M} = \text{Mn, Re} \\
\text{Cp(L)}\text{NiSnCl}_3 + \text{PbEt}_4 & \rightarrow \text{Cp(L)}\text{NiSnEt}_3 \quad (162) \\
\text{L} = \text{PR}_3, \text{AsR}_3, \text{CyNC}
\end{align*}
\]

In equation 160, similar substitution by Ph groups may be effected using HgPh, and halogen substitution in \((\text{CpFe})_2\text{SnR}_2\text{X}\) \(\{\text{X} = \text{I, Br, R} = \text{CH_3(SiMe}_3\}_2\}\) occurs upon treatment with NaOMe, K[HBEt3] or [Bu4N]F to give [Cp2(MoSnR2)(OMe)], [Cp(CO)2FeSnR2H] and [Cp(CO)2FeSnR2F], respectively. The hydride reacts with benzoyl chloride to form [Cp2(MoSnR2)Cl].

6. Reactions at the transition metal center

There are many reactions of metal–tin complexes where the tin group is a spectator ligand. The majority of these reactions are simple ligand substitutions, typified by the chemistry outlined in equations 163, 164, 165.

\[
\begin{align*}
\text{Cp(CO)}_2\text{FeSnR}_3 + \text{L} & \rightarrow \text{Cp(CO)(L)FeSnMe}_3 + \text{CO} \quad (163) \\
\text{R} = \text{Me, Ph, Cl; L} = \text{PR}_3 \quad \{\text{R'} = \text{Ph, OPh}, \text{Ph}_2\text{C}_2\} \\
\text{[Cp}_2\text{(PhCH=CH}_2\text{)NbSnMe}_3 + \text{L} & \rightarrow \text{[Cp}_2\text{(L)NbSnMe}_3 + \text{PhCH=CH}_2 \quad (164) \\
\text{L} = \text{CO, MeCN, 1,3,5-Me}_2\text{C}_6\text{H}_3\text{CN}, \text{PMe}_3 \}
\end{align*}
\]

Hydride abstractions (equations 166 and 167) and oxidative additions to form mixed silyl/stannyl complexes are also reported.

\[
\begin{align*}
\text{[Cp}_2\text{(H)NbSnMe}_3 + \text{KH} & \rightarrow \text{[K(crown)][Cp}_2\text{(H)NbSnMe}_3 \quad (166) \\
\{(\eta^6-\text{arene})\text{(CO)}_2\text{Cr(H)SnPh}_3 + \text{KH} & \rightarrow \text{K(\eta^6-\text{arene})(CO)}_2\text{CrSnPh}_3 \quad (167) \\
\text{arene} = \text{C}_6\text{H}_6, 1,3,5-\text{Me}_3\text{C}_6\text{H}_3, 1,2,4,5-\text{Me}_4\text{C}_6\text{H}_2 \text{and Me}_4\text{C}_6 \\
\text{Cp(CO)}_2\text{FeSnPh}_3 + \text{HSiR}_3 & \rightarrow \text{Cp(CO)Fe(SnPh}_3)(\text{SiR}_3)\text{H} \quad (168) \\
\text{R}_3 = \text{Ph}_3, \text{MePh}_2, \text{P(OPh)}_3, \text{AsPh}_3 \text{and SbPh}_3, \text{PMe}_3 \\
\text{Photochemical reaction of Cp(CO)}_2\text{FeSnPh}_3 \text{with diphenylacetylene gave 39\% carbonyl substitution product Cp(CO)(PhC=CHPh)FeSnPh}_3 \text{and 10\% 2,3-diphenylindanone.} \quad (169)
\end{align*}
\]

Similarly, the CO groups in Ph3SnCo(CO)4, (CO)3SnCo(CO)4 and Bu2Sn[Co(CO)_4]2 can be replaced by both mono- and bidentate phosphines (L) and in the latter case can lead to new cluster. While the tin is usually unaffected by these substitutions, such chemistry can sometimes be used to synthesize further metal–tin complexes. Thus, the deprotonation of Cp2(H)MoSnPh3 with BuLi gives Li[Cp2MoSnPh3], which on further treatment with ClSnMe3 yields Cp2Mo(SnPh3)(SnMe3).
The formation of transition-metal carbene complexes containing tin substituents on the metal is another example where the tin group is a spectator ligand (equations 169–171) 395–401.

\[
\text{Cp(CO)}_3\text{MSnPh}_3 + (a)\text{LiPh}/(b)\text{Et}_3\text{O}^+ \rightarrow \text{Cp(CO)}_2[\text{Ph(ETO)}]\text{MSnPh}_3
\]

\[
M = \text{Mo, W; Cp = C}_5\text{H}_5, C_5\text{H}_4\text{Me and indenyl(η}_5\text{-C}_9\text{H}_7)\]

\[
[\text{CpM(SnPh}_3)(\text{CO})(\text{COCH}_2\text{R})]^− + \text{AcCl} \rightarrow [\text{CpM(SnPh}_3)(\text{CO})(\text{C(OCOMe)}\text{CH}_2\text{R})]^{-}
\]

\[
\text{CpM(SnPh}_3)(\text{CO})(\text{C = CHR}) + \text{AcOH}
\]

\[
M = \text{Fe, Ru; R = H, Me, Pr, Ph}
\]

\[
(\text{CO})_3\text{ReSnPh}_3 + (a)\text{LiR}/(b)[\text{Et}_3\text{O}]^+[\text{BF}_4]^{-} \rightarrow \text{cis-(CO)}_4\text{ReSnPh}_3[\text{C(OEt)}\text{R}]
\]

\[
R = \text{Ph, NEt}_2, \text{N(Pr-i)}_2, \text{C}_6\text{H}_4\text{NMe}_2-4
\]

Methylamine and \(\text{Cp(CO)(CS)FeSnPh}_3\) react to give \(\text{Cp(CO)(C = NMe)FeSnPh}_3\), without affecting the Sn−Fe bond; under similar conditions ethylenediamine also forms a carbene complex (equation 172) 402.

\[
\text{Fe CO SnPh}_3
\]

\[
\text{Fe C = NMe SnPh}_3
\]

An unusual carbyne complex \(\text{Ph}_3\text{SnM(CO)}_4(\text{CNMe}_2)\) was obtained from the reaction of \([\text{Et}_4\text{N}]_2(\text{CO})_4\text{M(SnPh}_3)_2\)] (\(M = \text{Cr, Mo}\)) with \([\text{Me}_2\text{NCCl}_2]\text{Cl}\) 187.

The reaction of \(\text{Cp(CO)}_3\text{MSnPh}_3\) (\(M = \text{Mo, W}\)) with organolithium reagents produced carbene complexes of the type \(\text{Cp(CO)}_2\text{MC(OR')R}\) (\(R = \text{Me, Ph, R'} = \text{Me, Et}\)) 395.

7. Stannyl group migrations

The treatment of \(\text{Cp(CO)}_3\text{MSnR}_3\) (\(M = \text{Mo, W}\)) with lithium diisopropylamide (LDA) results in deprotonation of the cyclopentadienyl ring, followed by migration of the SnR3 group to the organic ring; after quenching the metallate anion with methyl iodide the product \((\eta^5\text{-R}_3\text{SnC}_3\text{H}_4)\text{M(CO)}_3\text{Me}\) can be isolated (see, for example, equation 52 for the related germanium migration) 403. Treatment of \([\text{CpM(CO)}_3]_2\text{SnMe}_2\) (\(M = \text{Mo, W}\)) with LDA results in double migration products (equation 173), but with one equivalent of LDA a single migration product can be isolated 155. Similar single and double migrations occur from Fe to the cyclopentadienyl group when the analogous Fe complexes \(\text{CpFe(CO)}_2\text{SnR}_3\) (\(R = \text{Me, Ph}\)) are treated with LDA 404.
Triphenylstannyl group migration also occurs on treatment of ethoxy carbene complexes of the type Cp(CO)₂{PhC(OEt)}MSnPh₃ (M = Mo or W) with LDA/HMPA, with formation of carbyne complexes [(η⁵-Ph₃SnC₅H₄)(CO)₂CPh], after treatment with PhC(O)Cl₄⁰⁵.

8. Photolytic reactions

Several miscellaneous reactions involving photolysis of metal–tin complexes have been reported. In the presence of carbon dioxide the photolysis of [Cp₂(PhCH=CH₂)NbSnMe₃] yields a mixture of [Cp₂(CO)NbSnMe₃] and [(Cp₂NBnMe₃)₂(μ-O)] by cleavage of the CO₂ molecule. Photolysis of Cp(CO)₂FeSnMe₃ in a stream of butadiene in benzene solution gave [Me₃SnFe(CO)₂C₄H₆]. Similarly prepared was Cp(C₄H₆)FeSnPh₃. UV irradiation of [(η⁵-C₇H₈R)(CO)₃CrSnPh₃ (C₇H₈, cyclopentadienyl; R = H, CPh₂)] with two equivalents of 2-butyne or 3-hexyne gave tricyclic complex compounds, by reactions in the organic side groups, with loss of the Cr–SnPh₃ moieties.

9. Other reactions

The reaction of [Et₄N]₂[(CO)₄M(SnPh₃)₂] (M = Cr, Mo) with acetic acid gave a 40% yield of the protonated product [Et₄N][H(CO)₄M(SnPh₃)₂]¹⁶. Also, the complexes [(CO)₃M(SnPh₃)₃]⁻³ are protonated by Bronsted acids to form [H(CO)₃M(SnPh₃)₃]⁻² (M = Cr, Mo, W)¹⁹⁷.

Reaction of the anionic complexes [Cp₂MSnPh₃]⁻ (M = Mo, W) with HgX₂ (X = Br, I) in THF results in the formation of di- and trinuclear compounds Cp₂(M₃SnHgX or [Cp₂(P₃SnM)₂Hg, without M–Sn bond cleavage. Similarly, with ZnBr₂ and CdCl₂ the trinuclear complexes [Cp₂(P₃SnM)₂M']₂M' (M' = Zn, Cd) were formed.

The lability of the Sn–C bond in metal complexes is further illustrated by an interesting methyl group migration between osmium and tin. Treatment of Me₃SnOsCl(CO)(PPh₃)₂ with either pyridine or sodium acetate resulted in the formation of (ClMe₂SnOs(Me)(py)(CO)(PPh₃)₂ and (AcOMe₂SnOs(Me)(CO)(PPh₃)₂, respectively. Furthermore, the migration is reversible and treatment of (ClMe₂Sn)Os(Me)(py)(CO)(PPh₃)₂ with carbon monoxide yields Me₃SnOsCl(CO)(PPh₃)₂.

10. Synthetic utility of tin copper and tin zinc compounds

Trimethylstannyl cuprates are reactive toward unsaturated compounds and numerous organic syntheses involve their use as reagents, forming organotin derivatives which can be further converted into a broad variety of compounds. This topic is beyond the scope of this review, but the variety of reactions is briefly noted below. Thus, (R₃Sn)₂CuLi reacts with triple bonds of alkynes, acetylenic esters, acrylates (R = Bu), acetylene (R = Ph), with formation of vinylstannanes or allenes or with carbonylolefins (R = Me).
The reagents $\text{Me}_3\text{SnCu\cdot SMe}_2$ or $[\text{Me}_3\text{SnCuSPh}]\text{Li}$ react with alkynes to form stannylalkenes and related tin–copper reagents are also used for the stannylation of allenes.

The reagents $(\text{Bu}_3\text{Sn})_2\text{CuCNLi}_2$ and $(\text{Bu}_3\text{Sn})_2\text{CuCNLi}_2\cdot 2\text{LiCl}$ afford stannylcupration of terminal alkynes, acetylenes, allenes, enynes, propargylamines, enynols, enynals, acetylenic silyl ketones, propargylic sulfides, acetylenic ethers and aminoacetylenic ethers.

Organotin–zinc derivatives can be used as reagents in organic synthesis. Thus, the stannyl zincate complex $\text{Me}_3\text{Sn}()_2\text{Et}_2\text{ZnLi}$ reacts with alkoxy-unsaturated ketones to form five-membered ring heterocycles.

D. Reactivity of Metal Stannynes

The stannylene complexes $\text{CpR}(\eta^2\text{-C}_2\text{H}_4)\text{CoSn[CH(SiMe}_3\text{)]}_2$ ($\text{CpR = C}_5\text{H}_5$, $\text{C}_5\text{Me}_5$) react with 2-butyne to give different products. Thus, the $\text{C}_5\text{H}_5$ derivative affords hexamethylbenzene, the free stannylene and $\text{CpCo}(\eta^6\text{-C}_6\text{Me}_6)$ (equation 174) whereas in the similar reaction the $\text{C}_5\text{Me}_5\text{Co}$ derivative gives a stannacyclopentadiene complex (equation 175).

The hydroxo hydrido stannylene complex $\text{Co(\mu-OH)}(\text{H})\text{Co[Sn[CH(SiMe}_3\text{)]}_2\text{]}_2$ and its deuteriated analog were obtained by treating the ethylene complex $\text{Cp(\eta^2\text{-C}_2\text{H}_4)Co[Sn[CH(SiMe}_3\text{)]}_2\text{]}_2$ with $\text{H}_2\text{O}$ or $\text{D}_2\text{O}$.

Insertion of sulfur and selenium into the Co–Sn bonds of CpR(η²-C₂H₄)Co{Sn[CH(SiMe₃)₂]₂}₂ (CpR = C₅Me₅, C₅Me₄Et) give ternary Sn—Q—Co cluster compounds of the type Cp Co(µ-Q)₂Sn[CH(SiMe₃)₂]₂ (Q = S, Se), which can support reversibly either the removal or the addition of one electron (equation 176)³⁰¹,⁴³⁷.

\[
\begin{align*}
\text{Cp} & \text{Co(Sn(SiMe₃)₂)₂ + 2 S} \rightarrow \text{Cp} \text{Co(SnS(SiMe₃)₂)₂ (176)} \\
\end{align*}
\]
Some further reactions are of interest. Thus, the dimer \{\text{CpNiSn[CH(SiMe\textsubscript{3})\textsubscript{2}]\textsubscript{2}}\}\textsubscript{2} reacts with water to cleave a Ni−Sn bond with formation of \text{CpNiSn[CH(SiMe\textsubscript{3})\textsubscript{2}]OH}, which contains a Sn−OH−Sn bridge; the reaction with MeCN leads to cleavage of a Ni−Sn bond, elimination of a stannylene molecule and formation of \text{Cp(MeCN)NiSn[CH(SiMe\textsubscript{3})\textsubscript{3}]OH}\textsuperscript{20}.

The nickel stannylene complex \{(C\textsubscript{2}H\textsubscript{4})\textsubscript{2}NiSn[CH(SiMe\textsubscript{3})\textsubscript{2}]\textsubscript{2}\} reacts with 1,6-heptadiene with conservation of the Ni:Sn bond to form \(\eta^2,\eta^2\text{-C}_7\text{H}_{12}\text{NiSn[CH(SiMe\textsubscript{3})\textsubscript{2}]_2}\) in quantitative yield\textsuperscript{317,438}. Both compounds react with butadiene, isoprene, PMe\textsubscript{3} and BPh\textsubscript{3} to give a variety of compounds which preserve the Ni−Sn bond\textsuperscript{438}.

The structural aspects of tin–transition metal complexes are well studied. Some recent examples of metal–tin single and double bonded complexes are provided in Tables 11 and 12.

V. ORGANOLEAD TRANSITION METAL COMPLEXES

Although the first transition metal–lead compounds were reported in 1941, their chemistry is less explored compared to the −silicon, −germanium and −tin analogs. This is predominantly due to a lesser stability, since they are prone to decompose thermally and this process is accelerated in the presence of light. Secondarily, it is important to recognize that organolead hydrides are largely unknown, or very unstable. As noted in the previous sections, both germyl and stannyl hydrides are important reagents for the formation of transition-metal complexes, therefore it is not surprising that less chemistry is reported for lead systems. There appear to be no significant reviews of the chemistry of the metal–lead bond.

A. Synthesis of the Transition Metal Lead Single Bond

Table 13 gives information on the availability of spectroscopic and crystallographic data for selected mononuclear transition metal–lead compounds and Table 14 gives similar data for the binuclear/polynuclear compounds.

1. Salt-elimination reactions between transition metallates and lead halides

The salt-elimination reaction involving the use of a transition metallate and organolead halides has been widely used to form metal–lead complexes (equations 177–179) and a range of such derivatives have been prepared for many metals, i.e. Cr\textsuperscript{7,484,485}, Mo\textsuperscript{7,484,485}, W\textsuperscript{7,484,485}, Mn\textsuperscript{35,486,487}, Re\textsuperscript{35}, Fe\textsuperscript{3,485,488−494}, Os\textsuperscript{37}, Co\textsuperscript{22,492}, Rh\textsuperscript{495} and Ir\textsuperscript{495}. The reaction of \(\text{Na}_2\{\text{M}_2(\text{CO})\textsubscript{10}\}\) (\(\text{M}=\text{Cr, Mo, W}\)) with PbX\textsubscript{2} resulted in the isolation of mononuclear anions \[\text{M}(\text{CO})\textsubscript{5}PbX\textsubscript{3}\] along with the formation of binuclear dianions \[\text{M}(\text{CO})\textsubscript{5}PbX\textsubscript{2}\]\textsuperscript{2−}, stabilized as their Ph\textsubscript{4}P\textsuperscript{+} or Bu\textsubscript{4}N\textsuperscript{+} salts (equation 179)\textsuperscript{496}.

\[
\begin{align*}
\text{M}^-\text{Na}^+ + \text{ClPbR}_3 & \rightarrow \text{M}^+\text{PbR}_3 + \text{NaCl} \\
(M=\text{Cr, Mo, W}) & R=\text{Me, Et, Ph} \\
[(\text{CO})\textsubscript{5}\text{Mn}]^-\text{Na}^+ + \text{Me}_3\text{PbCl} & \rightarrow (\text{CO})\textsubscript{5}\text{MnPbMe}_3 + \text{NaCl} \\
[M_2(\text{CO})\textsubscript{10}]^{2−} & \rightarrow [M(\text{CO})\textsubscript{5}PbX\textsubscript{3}]^- + [(M(\text{CO})\textsubscript{5})_2PbX\textsubscript{2}]^{2−}
\end{align*}
\] (177) (178) (179)

Highly reduced metal anions [M(CO)ₙ]³⁻ (M = Mn, Re; n = 4; M = Co, n = 3) react with two equivalents of Pb₃PbCl to provide anionic complexes that were isolated as crystalline ammonium salts (equation 180)⁴⁹⁷,⁴⁹⁸.

\[
[\text{Co(CO)}₃]³⁻3\text{Na}⁺ + 2\text{Pb}_3\text{PbCl} + \text{NH}_4\text{Cl} \rightarrow (\text{NH}_4)[\text{Co(CO)}₃(\text{PbPh}_3)₂] \quad (180)
\]

The reaction of [Fe₃(CO)₁₁]²⁻ with Pb₃PbCl in THF produced a unique iron cluster ¹¹⁵, which contains triangular Fe₃ core and a terminal Ph₃Pb group bonded to one of the Fe atoms, forming a linear Fe–Fe–Pb arrangement⁴⁹⁹.

The reaction of [Co(CO)₄]⁻Na⁺ and Pb(O₂CCH₃)₂ resulted in the formation of the cluster [Co(CO)₄]Pb containing four Co–Pb single bonds. The same material was also formed directly using metallic lead⁵₀⁰,⁵₀¹. A variety of anionic lead-iron clusters of different stoichiometry were obtained from the reaction of PbX₂ (X = Cl, O₂CCH₃) with [HFe(CO)₄]⁻ and their redox chemistry investigated⁵₀₂–⁵₀₄.

Heptacoordinated vanadium complexes of Pb were obtained by the direct reaction of V(CO)₆ with Ph₃PbCl in high yields (equation 181)

\[
4 \text{V(CO)}_6 + 3 \text{Ph}_3\text{PbCl} \rightarrow 3\text{(CO)}_6\text{VPbPh}_3 + \text{VCl}_3 + 6 \text{CO}
\]  

(181)

2. Synthesis from transition metal halides and organoplumbates

Complexes of Pd and Pt were synthesized by the reaction of cis- or trans- [ML₂Cl₂] (M = Pd or Pt; L = PEt₃ or AsEt₃) with triphenyllead lithium in ether at low temperature (equation 182). The red solution produced yellow crystalline solids of trans- [ML₂(PbPh₃)₂] complexes. These complexes are thermally stable; however, attempts to prepare the corresponding triphenylphosphine derivatives were unsuccessful.

\[
[\text{Pt(PEt}_3)_2\text{Cl}_2] + 2[\text{Ph}_3\text{Pb}]^-\text{Li}^+ \rightarrow \text{trans-[Pt(PEt}_3)_2(\text{PbPh}_3)_2] + 2 \text{LiCl}
\]  

(182)

3. Oxidative addition of Pb—Pb, Pb—C and Pb—Cl bonds to metal centers

The thermodynamic stability of lead–lead, lead–carbon and related bonds are considerably lower than those of their group 14 analogs Ge and Sn. Thus, the direct cleavage of such bonds in the presence of coordinatively unsaturated metal complexes presents a convenient route to the formation of a variety of metal–lead complexes (equations 183 and 184).
17. Transition metal complexes of germanium, tin and lead

\[(\text{Ph}_3\text{P})_4\text{Pt} + \text{Ph}_3\text{Pb} \rightarrow ((\text{Ph}_3\text{P})_2\text{Pt}(\text{PbPh}_3)_2) + 2 \text{Ph}_3\text{P}\]  \hspace{1cm} (183)

\[(\text{Ph}_3\text{P})_4\text{Pt} + \text{Ph}_4\text{Pb} \rightarrow ((\text{Ph}_3\text{P})_2\text{Pt}(\text{PbPh}_3)(\text{Ph})) + 2 \text{Ph}_3\text{P}\]  \hspace{1cm} (184)

The \(\text{Pb}−\text{Cl}\) bond of \(\text{R}_2\text{PbCl}_2\) (\(\text{R} = \text{Me}, \text{Ph}\)) added to the three-coordinate Pt(0) complexes \([\text{Pt}(\text{N}−\text{N})(\text{olefin})]((\text{N}−\text{N}) = \text{chelating nitrogen})\) to produce five-coordinate Pt(II) complexes \([\text{Pt}(\text{N}−\text{N})\text{Cl}(\text{R}_2\text{ClPb})(\text{olefin})]\). The isolation of these complexes was dependent upon the structure of the nitrogen base and the olefin.\(^5\)

Air-stable ruthenium complexes \([\text{Ru}(\text{Cl})(\text{EPh}_3)(\text{CO})_2(L−L)](L−L = N,N′-\text{diisopropyl}-1,4-\text{diaza}-1,3-\text{butadiene}, E = \text{Ge}, \text{Sn}, \text{Pb})\) were obtained by the decarbonylation of \(\text{Ru}(\text{CO})_3(L−L)\) followed by the oxidative addition of E−Cl to the 16e\(^−\) ruthenium complex (equation 185)\(^5\).

\[
\begin{array}{c}
\text{L}−\text{L}−\text{Ru}−\text{CO}−\text{CO}−\text{L}−\text{L} + \text{Cl}−\text{PbPh}_3 \rightarrow \text{L}−\text{L}−\text{Ru}−\text{CO}−\text{CO}−\text{Cl} + \text{CO} \\
\end{array}
\]  \hspace{1cm} (185)

4. Insertion of plumbylenes into a metal halogen bond

Addition of \(\text{PbR}_2\) to a benzene solution of iron complexes \([\text{CpFe}(\text{CO})_2\text{X}] (\text{X} = \text{I}, \text{Br}\) or Cl) resulted in the formation of four-coordinated functionalized Fe−Pb complexes, \([\text{CpFe}(\text{CO})_2(\text{PbR}_2\text{X})]\).\(^5\)

Ruthenium–lead clusters \(^{116}\) and \(^{117}\) containing bridging Pb atoms were obtained from the reaction of the plumbylene \([\text{Pb}\{\text{CH}(\text{SiMe}_3)_2\}_2]\) with \(\text{Ru}_3(\text{CO})_{12}\) in hexane at 60°C. Both clusters have a planar Ru\(_3\) triangle with bridging Pb and carbonyl ligands.\(^5\)

\[
\begin{array}{c}
\text{R}_2−\text{Pb}−\text{OC}−\text{Ru}−(\text{CO})_3 \quad \text{R}_2−\text{Pb}−\text{OC}−\text{Ru}−(\text{CO})_3 \\
\quad \text{(116)} \quad \text{(117)}
\end{array}
\]

5. Elimination reactions

An interesting approach for the synthesis of transition metal–lead bonds which has not been extensively explored involves the reaction of metal hydrides with \(\text{R}_3\text{Pb}−\text{X}\). The interaction of the Nb–H bond of \([\text{Cp}_2\text{NbH}_3]\) and the Pb–Cl bond of \(\text{Me}_3\text{PbCl}\) resulted in the isolation of a niobium lead complex\(^5\) with the elimination of HCl. Mo and W complexes \([((\text{Cp}_2\text{MH})_2(\mu−\text{Pb}(\text{O}_2\text{CMe}))_2]\) were also synthesized from metallocene dihydrides and trimethyllead acetate with the elimination of methane, \(\text{Me}_4\text{Pb}\) and other products. The formation of \(\text{Me}_4\text{Pb}\) by the cleavage of Pb–C bonds in the reaction is an indication that the reaction may involve monomeric \([(\text{Cp}_2\text{MH})(\text{PbMe}_2(\text{O}_2\text{CMe}))]\) as an
intermediate (equations 186 and 187) \((M = Nb, n = 3; M = Mo, W, n = 2)^{515}\).

\[
\begin{align*}
\text{Me}_3\text{Pb(O}_2\text{CMe)}_2 & \quad \text{Me}_3\text{Pb(O}_2\text{CMe)M} \quad \text{Pb(O}_2\text{CMe)}_2 \\
\text{Me}_3\text{PbCl} & \quad \text{Et}_3\text{N} \quad \text{PbMe}_3 \quad \text{H}_2
\end{align*}
\]

\[(186)\]

\[
\begin{align*}
\text{R}_2\text{E} & \quad \text{Fe(CO)}_4 \quad \text{B} \\
\text{R}_2 & \quad \text{Fe(CO)}_4 \quad \text{B} \\
\text{R}_2 & \quad \text{Fe(CO)}_4 \quad \text{B} \\
\text{R}_2 & \quad \text{Fe(CO)}_4 \quad \text{B}
\end{align*}
\]

\[(187)\]

**B. Transition Metal Pb(II) Complexes**

The types of spectroscopic data available for these compounds are given in Table 15. Dimeric group 14 bridged complexes \([\text{R}_2\text{PbMC}\text{(CO)}_4]_2\) \((M = \text{Mn and Fe})\) were obtained from the reaction of \([\text{M(CO)}_4]_2 + 2\text{Na}^+ + \text{R}_2\text{PbX}_2\) in THF. \(^{486,487,492,493,516}\) In the presence of donor solvents (B) like pyridine, THF, DMF and acetonitrile (B), these complexes undergo reversible cleavage of the metal–group 14 element bond to yield base-stabilized plumbylene metal complexes (equation 188)\(^{516}\).

\[
\begin{align*}
\text{OC}_4\text{Fe} & \quad \text{Fe(CO)}_4 \quad +2\text{B} \quad -2\text{B} \\
\text{OC}_4\text{Fe} & \quad \text{Fe(CO)}_4 \quad \text{ER}_2 \quad \text{B}
\end{align*}
\]

\[(188)\]

A simple route to obtain Mo–Pb(II) complexes involves the elimination reaction between the lead amide \(\text{Pb}[\text{N(SiMe}_3)]_2\) and two equivalents of molybdenum hydride \([\text{Cp}^R\text{Mo(CO)}_3\text{H}]\) \((R = \text{H, Me}_5 \text{ or SiMe}_3)_2\) (equation 189)\(^{517}\).

\[
\begin{align*}
[\text{Cp}^R\text{Mo(CO)}_3\text{H}] + \text{Pb}[\text{N(SiMe}_3)]_2 & \quad \longrightarrow \quad [\text{Cp}^R\text{Mo(CO)}_3]_2\text{Pb}
\end{align*}
\]

\[(189)\]

The related three-coordinate complexes \(\text{Mo}[\{\text{Cp}^R\text{Mo(CO)}_3\}_2\text{Pb(thf)}]\) were obtained as green crystalline solids in fairly good yield. Changing the reaction solvent from THF to a hydrocarbon resulted in the formation of an unusual bridging carbonyl dimeric Mo–lead complex \((\text{Cp}^*\text{Mo(CO)}_3)_2\text{PbCp}^*\text{Mo(CO)}_2(\mu\text{-CO})_2\), \(^{118}\)\(^{4c,517}\).

The anionic platinum–lead(II) complex \([\text{Pb} \{\text{Pt}(\text{C}_6\text{F}_5)_4\}_2]^{2-}\) in which the Pb atom is linearly bonded to two Pt atoms was obtained in methanol (equation 190)\(^{518}\).

\[
2(\text{Bu}_4\text{N})_2[\text{Pt}(\text{C}_6\text{F}_5)_4] + \text{Pb(NO}_3)_2 \rightarrow (\text{Bu}_4\text{N})_2[\text{Pb} \{\text{Pt}(\text{C}_6\text{F}_5)_4\}_2] + 2(\text{Bu}_4\text{N})_2(\text{NO}_3)
\]

(190)

A lead allene analog of Mn, 119, was prepared from the reaction of the thermally labile Mn complex \(\text{CpMn} \{\text{CO}\}_2(\text{THF})\) with \(\text{PbCl}_2\) as a reddish-brown air and light sensitive complex (equation 192)\(^{4d,519}\).

\[
\text{PbCl}_2 + \text{Mn} \stackrel{\text{PbCl}_2}{\longrightarrow} \text{Pb} = \text{Mn}
\]

(191)

The same allene analog 119 was obtained from the reaction of hydrido manganese complex \([\text{Cp}'\text{Mn}(\text{CO})_2\text{H}]^+\) with \(\text{PbCl}_2\)\(^{520,521}\). Treatment of 119 with excess of
CpMn(CO)$_2$(THF) yielded black crystals of the air-sensitive planar Mn$_3$Pb complex noted above.

C. Reactivity of the Transition Metal Lead Single Bond

1. Transition metal lead bond cleavage

Platinum–lead complexes undergo a cleavage of Pt–Pb bond with halogens and halogen acids. These reactions are believed to occur through an electrophilic attack on Pt(II) leading to oxidative addition with the formation of a hexa-coordinated Pt(IV) complex. Reductive elimination of a plumbane results in the observed products (equation 193).

\[
\text{Ph}_3\text{P} \begin{array}{c} \text{Pt} \end{array} \text{Et}_3\text{P} \begin{array}{c} \text{PbPh}_3 \end{array} + \text{HCl} \rightarrow \text{Ph}_3\text{P} \begin{array}{c} \text{Pt} \end{array} \begin{array}{c} \text{PEt}_3 \end{array} \begin{array}{c} \text{H} \end{array} \text{Cl} \begin{array}{c} \text{PbPh}_3 \end{array} \rightarrow \text{Ph}_3\text{P} \begin{array}{c} \text{Pt} \end{array} \begin{array}{c} \text{PEt}_3 \end{array} + \text{HPbPh}_3
\]

Hydrogen chloride attacks the Mn–Pb bonds to form lead chloride. To compare the reactivity of the M–H bond with the M–Pb bond in the [Cp$_2$MH$_2$(µ-Pb(O$_2$CMe)$_2$)] (M=Mo, W), the complexes were reacted with cyanoalkyne, HC≡C–CN; however, the only isolated product was Cp$_2$M[C(CN)=CH$_2]$.

2. Cleavage of the lead carbon bond

Halogenation of the binuclear Mn complex [Mn(CO)$_5$]$_2$PbPh$_2$ with Cl$_2$ or Br$_2$ cleaves the Pb–C bond rather than the Mn–Pb bond to produce halogenated Mn–Pb derivatives (equation 194, X = Cl, Br).

\[
[(\text{CO})_5\text{Mn}]_2\text{PbPh}_2 + 2\text{X}_2 \rightarrow [(\text{CO})_5\text{Mn}]_2\text{PbX}_2 + 2\text{PhX}
\]

No cleavage of the Mn–Pb bond was observed in these reactions and monohalogenated intermediates, [Mn(CO)$_5$]$_2$PbPhX, were not isolated.

3. Thermal and photochemical Studies

There are several reports concerning the thermal and photochemical reactivity of triorganolead metal complexes. In general they eliminate plumbylenes, R$_2$Pb, with a concurrent transfer of the organic radical to the metal center. Such chemistry is reported for platinum, iron and molybdenum inter alia. A typical reaction is outlined in equation 195.

\[
\begin{array}{c}
\text{OC} \begin{array}{c} \text{Fe} \end{array} \text{OC} \begin{array}{c} \text{PbMe}_3 \end{array} \rightarrow \text{OC} \begin{array}{c} \text{Fe} \end{array} \begin{array}{c} \text{Me} \end{array} + \text{PbMe}_2 \rightarrow 1/2 \text{Pb} + 1/2 \text{PbMe}_4
\end{array}
\]

The plumbylene species described, PbMe$_2$, disproportionated into metallic lead and Me$_4$Pb. This is analogous to the proposed mechanism involving 1,2-alkyl migrations from
Pb to Zn for the decomposition of alkyl lead chlorides in aqueous zinc slurry which are used for the removal of organolead compounds in industrial effluents. The disproportionation of the Pt complex \([\text{Pt(PPh}_3\text{)}_2(\text{PbPh}_3\text{)}_2]\) to \(\text{cis-}[\text{Pt(PPh}_3\text{)}_2(\text{PbPh}_3\text{)}\text{Ph}]\) is also believed to proceed through 1,2-phenyl migration from Pb to the Pt metal\(^{507,509}\). Upon photochemical treatment, the related lead complexes of group 6, \(\text{CpM(CO)}_3\text{PbMe}_3\) (\(\text{M} = \text{Cr, Mo and W}\)), behave in the same manner. However, the triethyllead complexes \(\text{CpM(CO)}_3\text{PbEt}_3\) (\(\text{M} = \text{Mo, W}\)) exhibit a different behavior and undergo disproportionation into bis-metal complexes (equation 196). Similar disproportionations were also observed in Mn\(^{486}\) and Fe\(^{492}\) complexes; e.g. the \(\text{Mn(CO)}_5\text{PbMe}_3\) complex in THF gave the bis-Mn complex, \([\text{Mn(CO)}_5]_2\text{PbMe}_2\).

\[\begin{align*}
\text{M-PbEt}_3 & \rightarrow \text{M-PbEt}_2
\end{align*}\]

(196)

The mechanistic details for these disproportionation reactions are not clear. It is possible that \(\alpha\)-elimination chemistry as outlined in equation 197 is involved, resulting in transient plumbylene metal complexes; however, no definitive data are available to substantiate such intermediates.

\[\begin{align*}
\text{M-PbR}_3 & \rightarrow \text{M-PbR}_2
\end{align*}\]

(197)

\[\text{4. Substitutions at the transition metal center}\]

Few examples of chemistry at the metal center, while maintaining the metal–lead bond, are reported. Usually, the reaction conditions are such that rupture of the metal–lead bond occurs. Nucleophilic substitution at Ru occurs when the product from the chemistry in equation 185 is reacted with Grignard reagents (equation 198)\(^{511}\).

\[\begin{align*}
\text{Ph}_3\text{Pb} & + \text{RMgX} \rightarrow \text{Ph}_3\text{Pb}
\end{align*}\]

(198)
Simple CO substitution by phosphine ligands has been observed for \([\text{(CO)}_4\text{Co}]_4\text{Pb}\) to produce a variety of phosphine-substituted clusters\(^{500,501}\). It is noteworthy that this compound does not contain organic substituents on lead.

**D. Reactivity of the Transition Metal Lead Double Bond**

There are few reports on the reactivity of the transition metal—plumbylene complexes. The allene analog of the Mn derivative \(119\) underwent oxidative addition of thiolate \(t\)-BuS\(^-\) to yield the trigonal-planar \(121\) (equation 199)\(^{521,523}\). The Pb—Mn bond length of 2.574(3) Å in \(121\) is longer than the bond length of 2.463(1) Å in \(119\) and the Mn—Pb—Mn bond angle is reduced to 135.5(1)° from the almost linear angle of 177.2(1)° found in \(119\). Changing the thiolate group to mesityl results in the isolation of anionic tetrahedral complex \(122\). The Mn—Pb bond in \(122\) undergoes further elongation to 2.617(3) Å and the angles around Pb atom are reduced to 118.2(1)—129.3(2)°. The Pb—S bond length of 2.594(6)—2.617(3) Å is also longer in comparison to the Pb—S bond length of 2.574(4) Å in \(121\).

Complex \(119\) also reacted with neutral nitrogen-containing ligands, bipyridine, 1,10-phenanthroline and TMEDA to form neutral complexes in which the Pb atom has a distorted tetrahedral geometry. The Pb—Mn bonds are longer (2.510—2.528 Å) than in the starting allene analog \(119\) but are shorter than the normal Mn—Pb single bonds. The Mn—Pb—Mn angles (146.9—149.4°) are also reduced from that of \(119\) and this, coupled to the elongation of the Pb—N bonds (2.535—2.559 Å), indicates the dative interactions of nitrogen\(^{520,523}\).

**E. Solid State Structures**

There are a limited number of structures reported for Fe—Pb complexes and these are recorded in Tables 16—18. For a series of iron carbonyl lead clusters, the Fe—Pb bond lengths vary from 2.624 Å for an electron-deficient three-coordinate planar Pb cluster \([\text{Fe(CO)}_4]_3\text{Pb}\) to 2.828 Å for a tetrahedral bridging anionic Pb cluster

²⁰⁷Pb NMR Spectroscopy

²⁰⁷Pb NMR spectroscopy is a valuable method for studying the transition metal–lead bond in solution and selected data are provided in Table 19. It is evident that the variations in chemical shift values with respect to the transition metal are large. Among all the transition metal–lead complexes, the lowest chemical shift value was observed for [Fe(CO)₄]₄Pb at 3587 ppm⁴⁹₃. Most of the data are available for metal carbonyl and metal phosphine complexes⁴⁹₃,5₂₄,5₂₅. The trends in chemical shift values are consistent with the trends observed in ²⁹Si and ¹¹⁹Sn NMR spectra of the corresponding transition-metal complexes where a comparison is possible. From the data available, it appears that the third-row transition metals exert a high field which has been interpreted as due to the higher polarizability of the transition metal and decreased capacity of the π-bonding between the transition metal and lead. Interestingly, the Pb chemical shift values are not dependent upon the concentration and the nature of the solvent, indicating a distinct lack of Lewis acidity for the Pb atom. The transition metal has a strong influence on the variation of chemical shift values due to the organic R group bonded to the lead. For example, in the iron series CpFe(CO)₅PbR₃, [CpFe(CO)₂]₂PbR₂ and [Fe(CO)₄(µ-PbR₂)]₂, introduction...

of Me, Et, and i-Pr produces a gradual low field shift$^{493}$. However, a different trend is observed in the Mo and W complexes of the type CpM(CO)$_3$PbR$_3$, where shielding increases in the sequence Et < Me < Ph, analogous to the trend observed in R$_3$PbX (R = Me, Et, Ph; X = Cl, Br, I).

Substitution of a carbonyl group by a phosphine ligand produces a high frequency shift. The extent of this shift is dependent upon the transition metal and organic group R. In Pt–Pb complexes, Pt(PPh$_3$)$_2$R(PbR$_3$) (R = C$_6$H$_4$X-4, X = H, Me, MeO, Cl, F), coupling constants $^1J$(Pb–$^{195}$Pt) range from 145 kHz to 18.5 kHz, the trans Pt–Pb compounds having the smaller coupling constants. Variation of the substituents on the phenyl groups had no apparent effect on the Pb chemical shift values$^{508}$.

II. INTRODUCTION

The use of organometallic compounds of group 14 elements for organic synthesis is undoubtedly overwhelmed by organotin chemistry, and in spite of increasing environmental considerations, the chemistry of organotins and its applications for organic synthesis continues to flourish during the years. In contrast, organogermanium and organolead applications decreased over the last decades up to the point of appearing anecdotic. Consequently, this chapter deals almost exclusively with organotin chemistry, reference being made to organogermanium or organolead chemistry when necessary.

However, it should be noted that all the applications of tin chemistry for organic synthesis cannot be covered comprehensively in this chapter, which is devoted to organotin compounds and to the reactivity of the metal–carbon bond. Tin hydride chemistry, which is of major importance in this field, is, for instance, treated in a separate chapter. For the same reasons, the numerous uses of tin(II) and tin(IV) reagents as Lewis acid or chirality inducers are not reported here as long as these reagents do not possess any tin–carbon bonds. Finally, the reactivity of the tin–oxygen bond (as a catalyst, or a protecting group) will not be mentioned in the following.
III. NUCLEOPHILIC ADDITION

A. Nucleophilic Addition to Carbonyl Compounds

1. Background

The addition of organotin reagents to carbonyl compounds remains a quite recent reaction compared to other organometallic reagents. This was presumably due to a lack of reactivity of the organotin, which necessitated thermal activation or high-pressure conditions. Consequently, the activation of the carbonyl partner by a Lewis acid, first reported in 1979, appeared to be the key factor in the increasing use of organotin reagents. The versatility of allyltin reagents enables one to achieve various orientations in the regio- and stereo-control of the addition and is regularly reviewed. Such selectivity depends on different mechanisms and transition states, which are closely related to the experimental conditions employed.

2. Lewis acid activation of the electrophile

a. Mechanisms and diastereoselectivities induced by γ-substituted allyltins. In contrast to the thermal or high-pressure activated reactions, which adopt a chair-like transition state, the Lewis acid promoted reaction proceeds via an open transition state, as the tin does not compete with the Lewis acid in the coordination to the carbonyl compound. The reaction leads to an excellent syn diastereoselectivity, first reported by Maruyama and coworkers, which was explained by proposing an antiperiplanar transition state. This proposal was completed by introducing a syn-clinal transition state to account for the syn selectivity, whatever the nature (E or Z) of the crotyl reagent (equation 1).
In contrast, it was reported that $\gamma$, $\gamma$-disubstituted allyltins reacted stereospecifically, the ($E$)-reagent giving a syn adduct and the ($Z$)-reagent giving an anti adduct. In such a case the reaction is assumed to proceed essentially via the syn-clinal acyclic transition state. It is noteworthy that $\alpha$-substitution on the allyltin reagent may affect dramatically the syn selectivity as well. This reaction was successfully extended to various $\gamma$-substituted allyltins, and applied in the total synthesis of complex frameworks achieved with excellent diastereoselections. The access to optically active $\alpha$-oxygenated allyltins and their subsequent rearrangement to $\gamma$-alkoxyallyltins allowed easy access to stereo-controlled 1,2 syn diols which were further applied for a synthetic purpose. Iterative use of allyltins enabled a rapid and efficient synthesis of a carbon chain containing several contiguous asymmetric centres (equation 2).

\[ \text{PMP} = p\text{-methoxyphenyl} \]

*b. Diastereoselectivity induced by chiral aldehydes.* The substrate plays an important role in the facial diastereoselection, particularly when there is an asymmetric centre
adjacent to the carbonyl group. In the general case, the approach of the allyltin is believed to follow the Felkin–Anh model giving the syn adduct 1 preferentially (equation 3)

\[ \begin{align*}
\text{anti (minor)} & \quad \text{syn (major) (1)} \\
\text{Nu:} & = \text{nucleophilic}
\end{align*} \]

However, a reversal of the diastereofacial selectivity may arise when the substrate has, in \( \alpha \) or \( \beta \) position of the side chain, a group prone to complexation with the Lewis acid. Then, the use of bidentate Lewis acids such as MgBr\(_2\), TiCl\(_4\) or ZnCl\(_2\) allows the reaction to proceed under a 'chelation control' model, providing preferentially the syn adduct for a 1,4-chelation and the anti adduct for a 1,5-chelation. This was exploited in the stereoselective synthesis of both diastereomers, simply by changing the chelation conditions on the substrate\(^{18}\). An impressive amount of work was done with various \( \alpha \)-alkoxy aldehydes\(^{19–23}\) as a route to carbohydrate chemistry. Similarly, \( \alpha \)-amino aldehydes were used as substrates for \( \beta \)-amino alcohol synthesis\(^{24,25}\).

It should be noted that when the reaction is conducted with a chiral aldehyde and a chiral \( \gamma \)-substituted allyltins, a ‘matching effect’ when both partners impose a convergent selectivity, or a ‘mismatching effect’ when the facial selectivity is divergent, may happen\(^{26}\). Such a stereoconvergent effect was used in the synthesis of the antitumour agent azinomycin\(^{27}\) (equation 4).

3. Activation of the allyltin reagent

a. In situ transmetallation. The activation of the allyltin may be performed by its transmetallation with the Lewis acid prior to the addition to the carbonyl. The first example was reported with SnCl\(_4\)\(^{28}\), but other Lewis acids such as TiCl\(_4\), AlCl\(_3\) or InCl\(_3\) may be used for the transmetallation. The main difference lies in the fact that the transient allyl metal has a stronger acid character than the starting allyltin, favouring the cyclic 6-membered transition state introduced by Zimmerman and Traxler\(^{29}\). Thus the diastereoselectivity of the reaction is different from that observed with an open transition state, with (\(E\))-crotyltin giving an anti selectivity, when (\(Z\))-crotyltin leads to a syn selectivity. We note
that the transmetallation proceeds via the allylmetal 2, which gives the thermodynamically favoured crotyltin 3 (equation 5). Then, under kinetic conditions, it remains possible to direct the reaction towards the formation of the ‘kinetic’ homoallylic alcohol.

\[
\begin{align*}
&\text{[Drawings and equations for reactions and structures]} \\
&\text{syn : anti} \geq 10 : 1
\end{align*}
\]

Under thermodynamic control, the homoallylic alcohol is obtained with an anti/syn selectivity up to 95 : 5.\(^3\) In order to prevent competition between the transmetallation and the complexation of the aldehyde, it is important that the allyltin reagent is added first to the Lewis acid. This is termed a ‘reverse addition’.

\[
\begin{align*}
&\text{[Drawings and equations for reactions and structures]} \\
&\text{‘Kinetic’} \\
&\text{‘Thermodynamic’}
\end{align*}
\]
b. Stereochemical outcomes.  

i. α-substituted allyltins. The easy and efficient access to enantiopure α-substituted allyltins associated to the transmetallation process is at the origin of impressive progress in the field of enantioselective synthesis. This is due to the ‘chirality transfer’ which occurs in the two steps of the reaction (equation 6).

\[
\begin{align*}
\text{SnBu}_3 \xrightarrow{\text{InCl}_3} \text{Cl}_2\ln \xrightarrow{\text{R}_2\text{CHO}} \text{InCl} \xrightarrow{\text{H}} \text{R}_1\text{Me(S)} \xrightarrow{\text{OH}} \text{R}_1\text{R}_2\text{H}
\end{align*}
\]

Thus efficient enantioselective synthesis of 1,2 diols can be achieved starting from enantio-enriched α-alkoxytins. However, in that case the use of a strong Lewis acid, such as TiCl₄, AlCl₃, SnCl₄ or ZnCl₂, causes a premature decomposition of the allyltin. Marshall and Hinkle circumvented this by using InCl₃ and applied it to the enantioselective synthesis of sugar-related compounds.

ii. γ-substituted allyltins. The enantiocontrolled preparation of δ-substituted allyltins has been used as well for the enantioselective synthesis of functionalized homoallylic alcohols. A major contribution is represented by a comprehensive study on various alkoxylated allyltins which, upon transmetallation with SnCl₄, gave intramolecularly coordinated trihalogenotins. This coordination appears to be essential either for its stabilization via a rigid cyclic structure, and for the transfer of the chirality by directing the addition on the less hindered face of the trihalogenotin. Interestingly, when using α-chiral aldehydes, the stereochemical induction of the tin reagent prevails over the substrate effect (equation 7). Efficient 1,4-, 1,5-, 1,6- and 1,7-asymmetric inductions were achieved in that way and have found application in the total synthesis of macrolides or a complex tetrahydrofuran.

4. Catalytic use of Lewis acid

Recent studies have been engaged in finding a catalytic version of the Lewis acid activated reaction. Bulky aluminium reagents may be used (5 to 10 mol%), for which the development of unfavourable interactions with the resulting tributyltin alkoxide moiety accounts for the decomplexation reaction. The method offers a good chemoselectivity, depending on the steric hindrance of the considered carbonyl compound. The catalytic effect of B(C₆F₅)₃ has been also evidenced, again with a good chemoselectivity, for which the reason is still under discussion. Lanthanide triflates (2 mol%) have been used as well, in the presence of stoichiometric amounts of benzoic acid in order to regenerate the Yb(OTf)₃ catalyst, ensuring a good turnover for the reaction. InCl₃ can perform allylation and alkynylation addition reactions catalytically, when associated to trimethylsilyl chloride as regenerating reagent. In that case, however, the nature of the solvent plays a role in the reaction efficiency.
an important role in favouring the transmetallation even with the ‘normal addition’ process. The transmetallation of allyltributyltin with catalytic quantities of dialkyldichlorotin leads to a more reactive allyldialkylchlorotin. The turnover of the catalytic system is maintained by HCl or Me₃SiCl. Finally, an association of triaryl methyl chloride as a Lewis acid and chlorosilane as the regenerating agent was described, giving promising results.

\]

5. Enantioselectivity

In parallel with the search for catalytic systems, an impressive amount of results in the field of enantioselective allylation has emerged (equation 8). The pioneering work of Marshall and Tang, using a chiral (acyloxy)borane 6 (CAB) system, was followed by titanium-based catalysts 7 and 8 leading to various homoallylic alcohols with enantiomeric excess up to 98%. Several variations of this system were reported replacing, for instance, Ti(OPr-i)₄ by Zr(OPr-i)₄ or ZrCl₄, leading to a more reactive catalyst, particularly suitable for the allylation of aromatic aldehydes. The use of activators, such as i-PrSSiMe₃, i-PrSBEt₂, i-PrSAEt₂ or B(OMe)₃, was realized for both systems. They are believed to accelerate the reaction by regenerating the Ti or Zr catalysts. Finally, one of the more active catalysts seems to be the zirconium–BINOL system associated with 4-t-butylcalix[4]arene,
which remains active with only 2% of the chiral inductor. It is noteworthy that the BINOL-Ti catalysed allylation was extended to ketones in good yields but with varied ee. In general, BINOL catalysts enable the replacement of the allyltin by crotyltin without lowering the yield or the enantioselectivity. β-Functionalized allyltin reagents were added with high levels of enantioselection, and such a strategy has been used in the total syntheses of macrolides.

Silver BINAP complex was used as well by Yanagisawa and coworkers. The particular feature of this catalyst is the marked anti selectivity when using crotyltins, regardless of whether the double bond is (E) or (Z). This selectivity is explained by a fast transmetallation step between the chiral complex and the organotin reagent, followed by the addition on the carbonyl group via a cyclic transition state. This reaction has been extended to other organometallics such as 2,4-pentadienylstannanes.

Catalysts with nitrogen ligands such as bisoxazolines have been introduced as Lewis acids. Recently, air-stable and water-resistant (Phebox)rhodium(III) complexes gave up to 80% ee.

6. Other organotin reagents

a. Activated allyltins. Replacing the butyl units by electron-withdrawing groups in order to activate the allyltin has been known for a long time and the replacement of allyltributyltin by tetraallyltin provided interesting results without any added Lewis acid. Some activation by alcoholic solvents or intramolecular participation of hydroxyl...
groups allowed the preparation of homoallylic alcohols under particularly mild conditions. However, most efforts have been focused on allyltin halide reagents. The first evidence of their reactivity dates back to 1978 and a scale of reactivity was established according to the Lewis acidity of the tin atom. They can be used in the presence of water, and when the allyltin halide is a transient reagent, electrochemically generated in situ, the allylation reaction can become catalytic in tin. Allyltin trihalides can be prepared easily and represent interesting reagents in the sense that the tin side products of the reaction are inorganic, allowing an easy purification. Moreover, they offer a solution to the problem caused by the toxicity of tributyltin residues. They have been largely used for the preparation of homoallylic alcohols in Barbier-type allylation reactions, and for the synthesis of α-methylene-γ-butyrolactones when starting from β-functionalized allyltins. The anti/syn selectivity is about 90:10 and is consistent with a cyclic transition state. Adjacent groups to the carbonyl may participate in the reaction by hexacoordinating the tin atom (equation 9) and creating a chelation control to determine the stereochemistry of the adduct.

The ability of allyltin halides to extend their coordination sphere allowed the preparation of chiral hypervalent complexes with diamine ligands, which have been efficient in the asymmetric synthesis of homoallylic alcohols with up to 82% ee. Similarly, a chiral hypervalent allyltin was prepared from a low valent tin (II) catecholate, chiral dialkyl tartrate and allylic halide. The allylation of aldehydes and activated ketones proceeded with high enantiomeric excess. Allyltins prepared from Lappert’s stannylene and allylic halides were shown to be efficient as well, although the Lewis acid character of the tin atom is much less marked in that case.

b. Allenyl- and propargyltins. Allenyl- and propargyltins are peculiar reagents in the sense that a possible interconversion between the two forms may occur, thus leading to a mixture of homopropargylic and homoallenic alcohols (equation 10). This isomerization is activated by Lewis acids, and may represent a serious drawback when
using a terminal alkyne as the organometallic reagent; however, it remains possible to obtain selectively both alcohols 12 and 13.

Complementary studies showed that it is possible to obtain selectively homoallenyl alcohols\textsuperscript{104} and homopropargyl alcohols\textsuperscript{105} when preparing \textit{in situ} the organotin reagent. The chemoselectivity remains outstanding with propargyl bromides leading exclusively to the homopropargylic alcohols 14 (equation 11).

The asymmetric approaches include the preparation of the configurationally stable chiral allenyltin starting from enantio-enriched propargylic precursors. When submitted to transmetallation with Sn, Bi or In Lewis acids before addition to the aldehyde, the homopropargyl alcohol is obtained in a 95 : 5 \textit{anti/syn} ratio and in a 90\% ee\textsuperscript{106}. On the other hand, the use of a chiral allenyltin reagent, without prior transmetallation, gives the \textit{syn} adduct selectively (95 : 5) (equation 12)\textsuperscript{107}. However, the use of chiral allenyltin and chiral aldehydes may lead to the same ‘match/mismatch’ effect that was observed with allyltins\textsuperscript{108,109}. Both approaches were applied to the synthesis of macrolides subunits\textsuperscript{110,111}.

The catalytic asymmetric allenylation has been explored with a BINOL/Ti system, giving selectively the homoallenyl alcohol with up to 95\% ee\textsuperscript{112}. Nevertheless, the lower reactivity of allenyltin compared to allylvin necessitated a nearly stoichiometric amount of 8. Recently, an improvement of the reaction by using \textit{i}-PrSBEt\textsubscript{2} overcame that limitation, making the system truly catalytic, with ee in the range of 81 to 97\%\textsuperscript{113,114}. Interestingly, this reaction showed an unexpected equilibration phenomenon, thus producing exclusively
the allenylation adduct irrespective of the propargyl or allenyl structure of the organotin reagent\textsuperscript{115}.

\[ \text{Piv} = \text{Me}_3\text{CO} \]

c. Buta-2,3-dienyltins. Recent studies on the synthesis and reactivity of buta-2,3-dienyltins showed their reactivity either with aldehydes or acetals when activated by BF\textsubscript{3} \cdot \text{Et}_2\text{O}, in producing butadien-2-yl methanol derivatives in good yields\textsuperscript{116}. In the same way, buta-2,3-dienyltins generated \textit{in situ} by the transmetallation of 1,3-butadien-2-yl tin with SnCl\textsubscript{4} reacted with various aldehydes to give the butadienyl adduct in 65 to 98\% yields\textsuperscript{117}. The asymmetric catalysed version with the BINOL/Ti/i-PrSBE\textsubscript{2} system was achieved with up to 98\% ee\textsuperscript{118}. 

\[ \text{Piv} = \text{Me}_3\text{CO} \]
d. Alkynyltins. The catalytic InCl$_3$ promoted allylation of aldehydes was extended to various alkynyltins, which were found to be highly reactive after a transmetallation reaction$^{119}$. The choice of solvent was found to be critical for ensuring that transmetallation occurs rather than complexation of the carbonyl substrate. The addition of alkynyltins to $\beta$-alkoxy aldehydes is reported to proceed with a 1,3-anti/syn selectivity reaching a ratio of 64 : 6 when using MeAlCl$_2$ as the Lewis acid$^{120}$.

e. Tin cyanide. Tin cyanide reacts even better than its silicon congener with $\alpha$-chiral aldehydes to give the cyanohydrins with excellent diastereoselectivities$^{121}$. A system using tin cyanide as catalyst and acetyl cyanide gives access to the acetylated cyanohydrins$^{122}$.

7. Conclusion

The allylation of carbonyl compounds with allyltin reagents is still an active area of organotin chemistry from the methodological point of view, and also for synthetic applications. For completeness we should add several alternative techniques, such as the development of trifluoromethanesulphonic acid as a Brønsted acid catalyst for the allylation of aldehydes in water$^{123}$, or the design of fluorous allyltin reagents for the platinum-catalysed allylation of aldehydes$^{124}$.

B. Nucleophilic Addition to Imines and Related Compounds

1. Reactions with imines

a. Introduction. In spite of the fact that the reactivity of allylmagnesium bromide towards imines was observed in 1957, the development of the addition reaction of allylmetals to imines remains quite recent. In contrast to more reactive allylmetals (e.g. M = Li, Mg, Zn), allyltins need the assistance of Lewis acid in order to react with imines. This was reported simultaneously by Trost and Bonk$^{125}$ with TiCl$_4$, and by Keck and Enholm$^{126}$ with TiCl$_4$ and BF$_3$·Et$_2$O. It was then demonstrated that TiCl$_4$ participated exclusively by activating the imine. Contrary to what was observed with aldehydes, a ‘reverse addition’ to favour the transmetallation reaction failed to give any homoallylic amine. Importantly, the transmetallation route remained effective with SnCl$_4$, so that Thomas and coworkers were able to extend the 1,5-asymmetric induction concept to the allylation of imines$^{127-129}$. Similarly to what has been observed with carbonyl compounds, the activation of the iminyl group can be achieved catalytically by using Ln(OTf)$_3$ as a Lewis acid$^{130}$.

b. Mechanisms and diastereoselectivity. It should be noted that allyborons and allyltins are the only allylmetals to add regioselectively to imines, providing exclusively $\gamma$-adducts$^{131}$. The stereochemistry of the addition was explained by Yamamoto and coworkers$^{132}$, using two sets of models to predict the syn/anti selectivity. One possibility could be a reaction via a cyclic transition state with the tin atom interacting with the lone pair of the nitrogen, giving four possible conformations depending on the position of the substituents. An alternative proposal suggested anti-periplanar or syn-clinal open transition states. The main difference between the two models lies in the fact that changing the $E/Z$ stereochemistry of the imine would result in a reversal of the syn/anti selectivity by applying the cyclic model, but it would give the same result with the open model. All the models presented for the diastereofacial selectivity in the case of carbonyl compounds are still valid for the imines. However, it has to be kept in mind that, due to the substitution on the nitrogen atom, imines can possess an additional chiral auxiliary which
can influence the diastereoselectivity. For instance, the use of carbohydrates as chiral templates orientated the SnCl$_4$ activated reaction of allyltributyltin with $N$-galactosylimines to give high asymmetric induction$^{133}$. Consequently, the introduction of chiral centres on both the carbonyl and the amine moiety of the substrate may cause match or mismatch effects$^{134}$.

The first example of 1,2-asymmetric induction was reported by Yamamoto and coworkers with $N$-propylaldimines derived from $\alpha$-phenylpropionaldehyde (equation 13). The reaction gave mainly the $anti$ product$^{135}$, consistent with a Felkin–Ahn addition. A 1,3-asymmetric induction took place with the imine prepared from 1-phenylethylamine and isovaleraldehyde, giving a somewhat lower 7 : 1 diastereoselectivity.

\end{align*}
\]

\[
\begin{align*}
\end{align*}
\]

Crotyltins react regioselectively with $\alpha$-alkylimines to give exclusively branched products with an excellent $syn/anti$ selectivity up to 30 : 1, when the imine activation is conducted at $-78^\circ$C prior to the addition of the crotyltin. This selectivity which is consistent with an acyclic transition state is rapidly fading when operating at a higher temperature. This would be the result of an equilibrium between the two imine/Lewis acid complexes (equation 14). There are very few examples with $\alpha$, $\beta$-unsaturated aldimines, but it has to be noted that under TiCl$_4$ activation, they are able to undergo a double nucleophilic addition of ketene silyl acetal and allyltributyltin to give the homoallylic amine in a reasonable yield$^{136}$.

\[
\begin{align*}
\end{align*}
\]

2. Other imino substrates

a. Reactions with $N$-heterosubstituted imines. These reagents may be used as ‘protected’ imines which, upon allylation and deprotection, give an access to primary homoallylic amines. For instance, the use of benzoyl- and acylhydrazones as stable surrogates of
imines was exploited in allylation reaction with tetraallyltin\textsuperscript{137,138}. Finally, nitrones can be used as substrates for the allylation reaction, giving access to homoallylic hydroxylamines\textsuperscript{139,140}.

\textit{b. Reactions with iminium salts.} Iminium salts are widely used substrates in order to overcome the lack of reactivity of imines. Thus, the reaction of allyltins with iminium salts, prepared from primary amines and formaldehyde, in protic media give access to bis(homoallyl)amines\textsuperscript{141,142}. Most of the iminium salts are prepared \textit{in situ}. Examples are acyliminium salts, generated from the corresponding \(\alpha\)-ethoxycarbamates which were shown to react with \(\gamma\)-alkoxyallyltins to give \(\alpha\)-amino alcohols in good yields. The \textit{syn/anti} selectivity depends on the nature of the iminium substituents\textsuperscript{143}. This reaction has been extended to various cyclic \(\alpha\)-alkoxycarbamates with high diastereoselectivities\textsuperscript{144}. Chiral acyliminium salts were used for the preparation of enantiopure piperidines\textsuperscript{145}. Lately, the addition of enantio-enriched \(\gamma\)-alkoxyallyltins to chiral acyl iminium salts\textsuperscript{146} provided a new entry to the synthesis of products 15, which are potential precursors of \(\alpha\)-amino-\(\beta\)-hydroxy acids or of aminosugars, with a total control of the stereochemistry (equation 15). Imines can be activated as well by Me\textsubscript{3}SiCl to give the corresponding iminium salts, which are reactive enough to undergo the allylation reaction with allylttributyltin\textsuperscript{147}.

\begin{equation}
\text{EtO}_2\text{C}^+\text{N}^+\text{CH}_2\text{Ar}^+ \text{MeOBDPS}(R) \begin{array}{c} \text{MOMOM} \text{SnBu}_3^- \end{array} \begin{array}{c} \text{BF}_3\cdot\text{OEt}_2, \text{CH}_2\text{Cl}_2, -78 \text{ °C} \end{array} \rightarrow \text{EtO}_2\text{C}^-\text{N}^-\text{CH}_2\text{Ar}^- \text{MeOBDPS} \text{OMOM} \text{BDPS} = t\text{-Bu(Ph}_2\text{)Si} \end{equation}

\textit{c. Reactions with pyridines and pyridinium salts.} Allyltins react as well with substrates such as pyridines or pyridinium salts selectively at the \(\alpha\) position\textsuperscript{148}. The \(\alpha\)- and \(\delta\)-regioselectivity of the addition is closely related to the substitution of the allylmetal reagent. An enantioselective approach was applied with a chiral acyl chloride as activator and an enantioselectivity inductor\textsuperscript{149}. Similarly, oxazolidinones were used as chiral auxiliaries, to promote the synthesis of chiral 1,4-dihydropyridines\textsuperscript{150}.

3. \textit{Catalytic enantioselective addition}

Among the increasing amount of work related to the catalytic enantioselective addition to imines, which appeared in the last 5 years\textsuperscript{151}, some papers were associated with organotin reagents. The first example of catalytic enantioselective allylation of imines was reported by Yamamoto and coworkers, by using 5\% of a bis \(\pi\) allyl palladium complex\textsuperscript{152–154}. Contrary to the BINAP ligand which was found to be totally ineffective under these conditions, \(\beta\)-pinene ligands used as non-transferable allyl ligands gave up to 81\% ee. An extension to the intramolecular reaction of \(\gamma\)-alkoxystannane was applied to prepare \(\beta\)-amino cyclic ethers, for which the \textit{trans} preference in the cyclization is
consistent with an acyclic transition state\textsuperscript{155}. A recent contribution showed that TolBINAP-CuX catalysts were also efficient for the allylation of $N$-tosyl imines\textsuperscript{156}, giving access to $\alpha$-amino acids with up to 98\% ee (equation 16). A polymer-supported version of Yamamoto’s catalyst has been recently prepared, giving moderate ee (13–47\%), but showing promising results in terms of stability and reusability\textsuperscript{157}.

![Image of reaction](image)

\textbf{4. Other organotin reagents}

The use of transition metals to increase the reactivity of allyltins towards imines or related substrates permitted the extension of the reaction to various other organotin reagents. Thus, a recent rhodium-catalysed arylation and alkenylation of imines was described by using 2\% molar of a $[\text{Rh(cod)(MeCN)}_2]\text{BF}_4$ catalyst, affording the corresponding amines in good yields\textsuperscript{158}. An asymmetric version was developed for the rhodium catalysed arylation of $N$-alkylidene sulphonamides, with the chiral monodentate phosphine ligand $(R)$-MeO-MOP giving the amines with ee in the range of 75 to 96\%\textsuperscript{159}. The enantioselective synthesis of an $\alpha$-aminonitrile was achieved in up to 86\% ee, by a zirconium-catalysed asymmetric cyanation reaction\textsuperscript{160}.

\section*{IV. METAL-CATALYSED COUPLING REACTIONS}

\textbf{A. The Stille Coupling Reaction}

\textit{1. Historical background}

\textit{a. Introduction}. The coupling reactions involving organotin reagents catalysed by transition metals are without any doubt the most prolific reactions in the literature. The very first example of this reaction dates back to 1977 with the pioneering work of Kosugi, Shimizu and Migita\textsuperscript{161,162}. However, the reaction is known as the Stille coupling, due to its mechanistic studies and synthetic applications by Stille and coworkers which definitely popularized this reaction\textsuperscript{163,164}. Nowadays, the versatility of tetraorganotins in terms of synthesis and reactivity render this reaction by far the most popular pallado-catalysed coupling along with the Suzuki reaction, involving organoborons. It has been regularly
reviewed\textsuperscript{165–168} and to be strictly correct it would be more accurate to talk about several Stille couplings, due to the impressive mass of different substrates, catalysts, ligands and experimental conditions which were used.

\textit{b. Mechanism.} A deliberately oversimplified catalytic cycle could be represented as shown in equation 17: (i) Formation of the active Pd(0) species, (ii) oxidative addition, (iii) transmetallation step, (iv) reductive elimination.

\[
\text{Pd(II)} \xrightarrow{(i)} \text{R}^1\text{Sn(R}^2\text{)}_3 \xrightarrow{(ii)} \text{R}^1\text{-R}^1 \xrightarrow{(iii)} \text{R}^3\text{-Pd(II)L}_n \xrightarrow{(iv)} \text{R}^3\text{-Pd(II)L}_n^\circ - \text{X} \xrightarrow{(17)} \text{R}^3\text{-Pd(II)L}_n^\circ - \text{R}^1 \xrightarrow{\text{transmetallation}} \text{XSn(R}^2\text{)}_3 \xrightarrow{\text{reductive}} \text{elimination} \xrightarrow{\text{oxidative}} \text{addition} \]

The active palladium catalyst is likely to be a coordinatively unsaturated Pd(0) species such as Pd(PPh\textsubscript{3})\textsubscript{2}\textsuperscript{169}. It can be obtained (i) either by reduction of a Pd(II) precatalyst\textsuperscript{170} or by the \textit{in situ} loss of ligands from a Pd(0) species\textsuperscript{171}. In the latter case the ratio Pd versus ligand is often found to be critical for the kinetic of the reaction. The first step of the catalytic cycle is the addition of the electrophilic substrate R\textsuperscript{1}-X to the palladium catalyst (ii), which goes up to a Pd(II) oxidation state and is favoured by σ-donor ligands\textsuperscript{172}. The mechanism of the oxidative addition depends on the nature of the electrophile. With an aromatic, alkenyl or alkynyl substrate, the catalyst would insert into the carbon–halogen bond via a three-centre mechanism\textsuperscript{173}, preserving the olefin stereochemistry. With substrates possessing an sp\textsuperscript{3} carbon–halogen bond, the mechanism would account for an S\textsubscript{N}2 reaction with inversion of asymmetric centres\textsuperscript{174,175}. This oxidative addition is believed to form primarily the \textit{cis} complex, which readily isomerizes to the thermodynamically favoured \textit{trans} complex\textsuperscript{176–178}. With the allylic substrates, the intermediacy of η\textsuperscript{3}-complexes is postulated\textsuperscript{179}. However, the reaction appears to be ligand and solvent dependent as well\textsuperscript{180}. In addition to this, recent results showed that the nucleophile itself could intervene in the kinetics of the oxidative addition step\textsuperscript{181}. 
The transmetallation step (iii) is certainly the most enigmatic part of the catalytic cycle. Generally, it is assumed to be rate limiting, and several mechanisms are proposed depending on the solvent. An ‘open’ transition state with inversion of the stereochemistry would arise with polar solvents which are able to stabilize the transient partial charges\textsuperscript{182,183}, whereas a cyclic transition state with retention of the stereochemistry would arise in less polar solvents\textsuperscript{184}. It should be noted that the nature of the ligands on the palladium may influence dramatically the kinetics of the transmetallation step. A 1000-fold rate enhancement was observed when replacing triphenylphosphine by tri(2-furyl)phosphine\textsuperscript{185}. However, the dissociative or associative nature of the substitution on the palladium is still under discussion\textsuperscript{186,187}.

The reductive elimination step (iv) is a three-centre mechanism, which creates the carbon–carbon bond, regenerates the catalyst and needs the R\textsuperscript{1} and R\textsuperscript{3} groups to be cis on the palladium. This may be the case when cis bidentate ligands are used\textsuperscript{188}. On the other hand, a trans to cis isomerization may precede the reductive elimination, which operates through T-shaped Pd(II)\textsuperscript{189,190} or Pd(IV)\textsuperscript{191–193} intermediates. Finally, recent studies argued that a T-shaped three-coordinate species cis-[PdR\textsuperscript{1}R\textsuperscript{2}L] may be formed directly by an associative transmetallation step.

2. Scope and limitations

a. Organotins. i. Alkynyltins. Alkynyltins are considered to be the most reactive organotins\textsuperscript{194}, so that the coupling reaction with alkynyltins operates smoothly and offers an elegant solution to the synthesis of several conjugated systems. The reaction takes generally a few minutes at room temperatures\textsuperscript{195}; however, this high reactivity is not a limitation to their use in tandem reactions such as that shown for the dienyne in equation 18\textsuperscript{196}. The only limitation lies in the fact that alkynes themselves are able to couple with electrophiles in the Sonogashira coupling, simply by adding an amine as a base and copper salts\textsuperscript{197}.
ii. Alkenyltins. The use of alkenyltins has been thoroughly explored for both intermolecular and intramolecular reactions. The reaction tolerates a wide range of functionalities such as aldehydes, ketones, esters, unprotected alcohols, ethers and amines. Importantly, the transfer of alkene operates with a retention of the double-bond stereochemistry. Indeed, most of the observed isomerizations occurred after the coupling reaction\(^\text{198}\). Moreover, the reaction is not affected by the steric hindrance of the electrophile\(^\text{199}\). Nevertheless, a substitution in \(\alpha\) or \(\beta\) position of the tin atom may lower in some cases the yield of the reaction\(^\text{200}\). Allenyltins may be used as well, leading to allenyl\(^\text{201},\text{202}\) or propargyl\(^\text{203}\) transfer products, depending on the nature of the substrate.

iii. Aryl- and heteroaryltins. Their reactivities are in the same range as those observed for vinyltins\(^\text{204}\). Both electron-poor or electron-rich groups are tolerated on the aromatic group without altering the reactivity, but an \(\text{ortho}\) substitution may exert an influence on it\(^\text{205},\text{206}\). Consequently, an \(\text{ortho}\) substitution on the organotin and/or the substrate appears to be the main limitation of the reaction\(^\text{207}\). This reaction was rapidly extended with success to heteroaromatic chemistry, to organic synthesis and to supramolecular chemistry. For instance, iterative Stille coupling reactions of substituted pyridines were used to prepare polydentate ligands\(^\text{208}\) (equation 19).

iv. Allyl- and benzyltins. The transfer of allyl and benzyl groups is possible, but their reactivity appears to be lower than with organotins possessing an Sn-Csp\(^2\) bond. Furthermore, when reacting with olefinic or aromatic substrates, the coupling products are prone to reconjugate under Stille coupling conditions\(^\text{209},\text{210}\). Another limitation consists in the loss of the regioselectivity when operating with \(\gamma\)-substituted allyltins, the results being strongly dependent on the nature of the substitution\(^\text{211–213}\).

v. Alkyltins. The transfer of an alkyl group by using organotins remains exceptional and necessitates harsh conditions\(^\text{214}\) (equation 20). As a consequence, methyl and butyl groups, which are considered as non-transferable ligands, do not usually interfere with the transfer of the aforementioned groups. However, some examples of methyl, ethyl and butyl transfers\(^\text{215–218}\) from the corresponding tetraalkyltins are known. The transfer of an alkyl substituent is nevertheless possible when the electrophile is \(\beta\)-substituted by a heteroatom to the tin, thus improving the nucleophilicity of the carbon to be transferred\(^\text{219}\). Interestingly, the transfer of the hydroxymethyl group from Bu\(_3\)SnCH\(_2\)OH does not require protection of the alcohol function\(^\text{220}\).

b. Substrates. i. Halide. Alkenyl and aryl halides are the most commonly used substrates for the Stille coupling reaction. The stereochemistry of the double bond is usually preserved, and the reaction takes place even with a tetra-substituted olefinic electrophile. Furthermore, functionalized substrates such as \(\beta\)-halo-\(\alpha,\beta\)-unsaturated ketones, esters\(^\text{221–223}\) or sulphoxides\(^\text{224,225}\), \(\alpha\)-halo-\(\alpha,\beta\)-unsaturated ketones\(^\text{226,227}\) or haloquinones\(^\text{228–231}\) are reactive.

Aryl iodides and bromides couple with most of the organotins, and the reaction is compatible with poly-substitution on the aromatic ring. As the insertion of the palladium into the C–Br bond requires more drastic conditions, the oxidative addition may become the rate-limiting step, so that the reaction can be accelerated by electron-withdrawing groups in the \(\text{para}\) position. Similarly to alkenyl chlorides, aryl chlorides do not generally react, due to their lack of reactivity in the oxidative addition to the Pd(0) catalyst. However, very recent results established that the cooperative effect of an electron-rich sterically hindered \((t\text{-Bu})_3\text{P}\) associated to a fluorne source results in the coupling of various organotins with aryl chlorides (equation 21)\(^\text{232}\).

Heteroaryl halides such as halopyridines\(^{233}\), bromoquinolines\(^{234,235}\), furyl halides\(^{236}\), thienyl halides\(^{237−241}\) and imidazoyl bromides\(^{242}\) were found to be reactive. A particularly interesting application concerns nucleoside chemistry, since 2-iodopurine\(^{243−246}\), 5-iodouridine\(^{247−249}\), 5-halouracil\(^{250−252}\) and 5-iodocytosine\(^{253}\) were used successfully. When the reactivity of the carbon–halogen bond is exalted, the coupling reaction can be extended to chloro derivatives, such as 6-chloropurines\(^{254}\), 4- and 5-chloropyrimidines\(^{255−259}\) and 2-chloropyrazines\(^{260}\).

In the same way, the coupling reaction of acyl chlorides and organotins is particularly efficient and general\(^{261}\). This represents an alternative to the ‘carbonylative’ three-component coupling reaction, and gives access to various aldehydes, ketones and \(\alpha, \beta\)-unsaturated ketones. A similar reaction is feasible with chloroformates, carbamoyl chlorides and sulphonyl chlorides, giving respectively \(\alpha, \beta\)-unsaturated esters, amides\(^{262}\) and sulphones\(^{263}\).

\(\text{ii. Sulphonates}\). The use of sulphonates was first observed in 1984\(^{264}\) and concerned essentially with organic triflates, which appear as the substrates of choice for the Stille coupling reactions. The rapid development in the field is due to the ready preparation of vinylic triflates from ketones and of aromatic triflates from phenols. However, triflates gave poor yields under usual Stille coupling conditions, presumably due to the formation of an unstable ionic palladium species\(^{265}\). In order to avoid the premature decomposition of the catalyst, it appeared necessary to add halide salts such as LiCl, to form the classical
Pd(II) intermediate. Another approach stated that LiCl was unnecessary when operating in polar solvents (DMF, NMP) which formed a solvated reactive Pd intermediate. As the solvent is believed to displace ligands out of the coordination sphere of the metal, the system was finally optimized by replacing the strong donating phosphine ligands by a softer triphenylarsine ligand. The overall understanding of the mechanism involving triflates is still under discussion.

In addition to the triflates, it can be noted that some attempts were made with mesylates, tosylates, p-fluorophenyl sulphonates, nonaflates and other polyfluorinated sulphonates and fluorosulphonates.

iii. Miscellaneous. The use of various salts, highly reactive towards nucleophiles, was applied in the Stille coupling. Trivalent iodonium salts such as phenyliodonium tetrafluoroborate or triflate were introduced in 1992. They undergo facile coupling reactions, under particularly mild conditions. Various vinyl-, aryl- and heteroaryl iodonium salts were prepared, and their use can be illustrated by the preparation of a potent antiviral uracil analogue (equation 22). A similar approach involves the use of aryldiazonium salts, and quite recently the efficiency of sulphonium hexafluorophosphates was established. In the particular case of allylic electrophiles, and due to their peculiar reactivity towards oxidative addition to the palladium, some unusual leaving groups such as chlorides, acetates or phosphates were found to be quite reactive. Interestingly, whereas propargyl acetates failed to react, allenyl acetates underwent the coupling reaction efficiently. The extension to vinyl phosphates was recently achieved and applied to the total synthesis of Brevetoxin A.

\[\text{c. Catalysts. Pd(PPh}_3)_4 \text{ is a widely used catalyst for palladium coupling reactions, but several studies demonstrated that it is not the best catalyst. However, there is no clear rule to point out what will be the ‘good’ catalyst for a given reaction, and several factors are}]

to be considered in order to optimize the coupling conditions. Farina demonstrated that an excess of ligand would inhibit the coupling by slowing the formation of the supposed coordinatively unsaturated PdL2 active species. The optimum ratio can be easily attained by replacing Pd(PPPh3)4 with the stable Pd2dba3 and the correct quantity of the phosphine ligand. Another possibility implies the use of the Pd(II)(PPh3)2Cl2 complex which is in situ reduced to the active PdPPPh32.

The nature of the ligand itself is of paramount importance for both the oxidative addition and the transmetallation steps. The replacement of a strong donating ligand such as PPh3 by softer ligands such as tri(2-furyl)phosphine125,185 or phosphites generally results in a great enhancement of the reaction rate. This is the case in coupling reactions involving triflates, in which triphenylarsine was shown to be particularly efficient. It is also possible to change the bulk of the ligand, e.g. by using P(Bu-t)3 in order to favour the ligand dissociation step232. Finally, it is noteworthy that several Stille couplings were conducted under ‘ligandless’ conditions without altering the stability of the catalyst294,295.

Cocatalysis with copper salts has proven its efficiency in the enhancement of the reaction rate, particularly in polar solvents. Discovered by Liebeskind and Feng296, and largely exploited, the cocatalytic effect of Cu(I) depends on the reaction conditions in two ways297,298 (equation 23). The copper acts as a ligand scavenger in polar solvents, thus enhancing the ligand/solvent exchange. It is also able to transmetalate with the organotin to produce an active organocopper reagent299. This interesting event was highlighted by the success of coupling reactions between organotins and halides conducted without palladium, and with CuCN as a catalyst300,301 or when mediated by CuCl302–304.

3. Synthetic applications

a. Intermolecular couplings. i. Vinyl–Vinyl couplings. Use of the Stille coupling reaction has found applications in several domains such as heteroaromatic chemistry, supramolecular chemistry, polymers and total synthesis. The major contribution of
Stille coupling to organic synthesis is the preparation of polyconjugated systems via the vinyl–vinyl coupling reactions. This methodology was used in carbohydrate chemistry, terpenoids chemistry and in preparing polyconjugated dienes. The enone functionalization can be performed either in α, β or γ position, and this was applied to leucotrienes synthesis. There were several uses in steroid chemistry and for the synthesis of complex natural molecules such as onnamide A, avermectin, calyculin, lepicidin, ratjadone, amphidinolide B and brevetoxin A. Interestingly, the synthesis of polyconjugated dienes involved frequently the use of (E,Z)- or (E,E)-dienyltins, and was applied to the synthesis of natural products such as Pateamine A, Nisamycin (equation 24) or Polycavernoside A.

The reaction has been extended to alkynyltin reagents due to the particularly smooth conditions allowed in these couplings. Various substrates such as enynes, vinyl ethers, α, β unsaturated esters, cyclobutenediones, quinones or chiral vinyl sulphoxides were reacted successfully. All the combinations are possible, so that ynynyltin, enynyltin and diynyltin reagents were used. Finally, distannylated reagents such as 1,2-vinylditin, 1,4-dienylditin or 1,2-ethynylditin were prepared in order to obtain double Stille coupling reactions.

**ii. Aryl–aryl couplings.** This reaction is particularly useful for different types of reactions, such as the preparation of ligands or cryptands, the design of materials with optical and electronic properties such as polythiophenes, the functionalization of more complex aromatic structures such as porphyrins and even the total synthesis of natural products or peptide receptors analogues. All types of aromatic systems were used including benzenes, pyridines, pyrroles, furans, thiophenes, pyrimidines and others. Furthermore, the reaction is particularly tolerant to functional groups or moieties such as fluorine or chlorine, trifluoromethyl, acetylenes, nitriles, ethers and thioethers, esters and amides, ketones and aldehydes, ketals, nitro, unprotected amines, hydroxyls or carboxylic acids. As outlined above, an ortho disubstitution may alter the reaction. However, there are several examples of couplings with o,o'-disubstitution either on the aromatic substrate or on both reaction partners. An interesting possibility of this reaction is related to the poly-substitution of aromatic systems, thus allowing 1,2-, 1,3-, 1,4- and 1,3,5-triple coupling reactions in one pot. Moreover, it is possible to conceive sequential couplings, depending on the intrinsic reactivity of each functionality of the substrate under a given experimental condition.

**b. Intramolecular coupling.** The intramolecular version of the Stille coupling, first reported in 1985, is a particularly attractive way to get rings ranging from four to thirty-two members. It is noteworthy that, contrary to the classical macrocyclization processes, the intramolecular Stille coupling does not require high dilution techniques to operate.

**i. Alkenyl–alkenyl cyclizations.** The elaboration of conjugated polyenic cyclic structures remains a major tool in the total synthesis of natural products. The retention of the stereochemistry of both the alkene electrophile and the alkenyltin, coupled with the mildness of the coupling conditions led to the advantageous use of the Stille coupling at the very end of the macrocycles synthesis. The alkenyl–alkenyl coupling permits the synthesis of small rings such as four, five, six-membered rings with exocyclic dienic system or with one internal double bond. Medium-sized rings from seven to fifteen members were also formed. It should be noted that ten-membered...
cycles with internal triple bonds can be obtained in good yields\textsuperscript{406,407}. The high potential of the intramolecular coupling was realized by several syntheses of macrocycles having, from fourteen- to twenty-nine-membered\textsuperscript{408} rings. In this series, either $Z/E$ dienes were prepared for the synthesis of leynamicyn\textsuperscript{409}, $Z/Z$ dienes were used for the synthesis of papuamine\textsuperscript{410} or an $E/E/E$ triene was used for the famous Nicolaou’s total synthesis of rapamycin using the aforementioned 1,2-vinylditin reagent\textsuperscript{411}. One of the most impressive examples for the potential of Stille coupling reaction is certainly the recent total synthesis
of Sanglifehrin A\textsuperscript{412}, for which the two key steps are an intramolecular vinyl–vinyl coupling to form the 22-membered ring, followed by an intermolecular vinyl–vinyl coupling to connect the spirolactamic side chain (equation 25).

\begin{align*}
\text{ii. Alkenyl–aryl cyclizations.} \text{ Cyclizations involving an alkenyl–aryl coupling reaction gave four–} & 413 \text{ to fifteen-membered} \text{ rings. The olefinic moiety can be extracyclic} & 415 \text{ or intracyclic with } Z \text{ or } E \text{ stereochemistry, depending on the substrate and the size of the ring to be formed} & 416 \text{ (equation 26). Other examples of heteroaryl–vinyl couplings can be found in the recent literature. An example is the approach to the synthesis of lophotoxin,}
\end{align*}
using a vinyl iodide and a 2-(tributylstannyl)furan coupling reaction.

\[ Z:E = 1:1 \]

ThF, reflux $\text{Pd}_2(\text{dba})_3, \text{P(2-furyl)}_3$ 1%  

SEM = Me$_3$Si(EtO)CH

iii. Aryl–aryl cyclizations. Aryl–aryl couplings gave cyclizations from six- to thirty-two-member rings, giving access to polyaromatic compounds, cryptands and heterocycles. A particularly interesting version is represented by the Stille–Kelly cyclization, which implies primarily a coupling between Bu$_6$Sn$_2$ or Me$_6$Sn$_2$ with an aryl halide to form \textit{in situ} the ArSnR$_3$ reagent ($R = \text{Me, Bu}$) which subsequently reacts with another Ar-X function to give the cyclized product (equation 27).

iv. Miscellaneous reactions. Advantage of the high reactivities of acyl chlorides and chloroformates was taken in order to obtain macrocycles having from seven to twenty-two members. This represents an interesting access to various cyclic ketones, lactones, $\alpha$-methylene lactones and $\alpha, \beta$-unsaturated esters. The carbonylative macrocyclization has been targeted as well to prepare $\alpha$-methylene lactones containing twelve- to sixteen-member rings. For such reactions, Pd catalysts supported on polymers were shown to be more selective than the classical homogeneous systems.

4. New trends in the Stille coupling reaction

a. Solid-phase supported reactions. The development of solid-phase chemistry and combinatorial chemistry in the last ten years has offered new fields of investigation to the Stille coupling reactions. The main advantage of the method is obviously related to the purification step, which allows one to free the product from tin residues. There are three different possible ways to employ the coupling reaction (equation 28):
18. Synthetic applications of organic germanium, tin and lead compounds

\[
\text{Bu}_6\text{Sn}_2 + \text{Toluene, reflux, 12 h} \rightarrow \text{Pd(PPh}_3\text{)}_2\text{Cl}_2 \ 5\%, \text{Et}_4\text{NCl} \rightarrow \text{68%}
\]

(iii) & \quad R^1 - X + R^2 - \text{Sn} \\
\end{align*}

(28)
(i) The substrate is in solution and the organotin is bonded to the polymer via the tin atom.
(ii) The substrate is in solution and the organotin is bound to the polymer via the organic moiety.
(iii) The substrate is grafted to the solid phase and the organotin is in solution.

**i. Organotin grafted on polymers.** The first approach is derived from the chemistry developed by Neumann’s and Pereyre’s groups among others, to get tin hydrides supported on polymers (see the preceding section). The organotin reagent is grafted on a polystyrene resin and the product is released into the organic phase and purified by filtration. The method was recently extended to an intramolecular coupling reaction used for the synthesis of the antibiotic zearalenone. The second approach was used for the synthesis of various benzodiazepines via an aryl–acyl chloride coupling already in 1995, and was further extended to the biaryl synthesis. The product, which is bound to the polymer, is purified from the tin residues by successive washings, before its cleavage from the resin. It is noteworthy that the reaction is believed to work better when the aryltin nucleophile is the one on the solid support (method ii versus method iii).

**ii. Substrate grafted on polymers.** The third method was first reported in 1994 for aryl–aryl and aryl–alkenyl couplings, and then extended to aryl–heteroaryl couplings and used for a phenyl–furan coupling on various supports frequently used in peptide chemistry, giving up to 90% yield. An extension of the method consists in developing sequential halogenation–Stille coupling reactions to get oligothiophenes, up to the pentamer, in 89% yield and excellent purity.

A general tendency for the three methods lies in the need to raise the Pd ratio up to 5–10% in order to avoid a too long reaction time. Nevertheless, the continuing search for new solid supports, linkers or palladium catalysts will ensure the development of the ‘supported Stille coupling reaction’.

**b. Unusual media.** In comparison with heterogeneous solid supported methods, the fluorous synthesis technique offers the advantage of the non-miscibility at room temperature and the homogeneity under heating. First developed by Curran and coworkers for tin-mediated radical chemistry (see the preceding section), the method was extended to the Stille coupling reaction in 1996. The method was recently improved by using microwave activation which enabled one to get coupling products in six minutes and up to 78% yield. The Stille reaction is easily adaptable to the emerging techniques, as shown by its successful use in aryl–vinyl couplings using supercritical carbon dioxide as the reaction medium. Likewise, the Stille coupling can be conducted in aqueous medium by using a Pd(II) catalyst and water-soluble phosphines, or a palladium complex supported on silica.

**c. Hypervalent organotin reagents.** The activating effect caused by an additional coordination to the tin atom was established in the early 1990s by Vedejs and coworkers and by Van Koten and coworkers. The formation of a hypervalent organotin is supposed to accelerate the limiting transmetallation step by increasing the nucleophilicity of the organic group to be transferred. Thus, the α-heteroalkyl-enol triflate coupling was used for the synthesis of carbapenem derivatives (equation 29) by means of Vedejs’ stannatrane. The affinity of a fluorine atom for the tin, the ease of halogen–fluorine exchange and the production of easily removable fluorotin side products encouraged several investigators to synthesize various fluorostannates as activated organotin reagents. However, in contrast with their silicon and boron counterparts, the use of fluorostannates...
for the Stille coupling remained limited until recently. The transfer of a phenyl group to vinylic triflates by using triphenyldifluorostannate was reported only in 1994, followed by an extension to various aryltins by using tetraorganofluorostannates. A promising approach using monoorganotins and TBAF as a fluorinating agent revealed the generality of the reaction to all kinds of organic moieties, including alkyl transfer which occurred in up to 76% yield. Furthermore, these reagents exhibited a specific reactivity compared to classical organotin reagents, such as a total γ-stereocontrol for the transfer of substituted allyltins (equation 30). This methodology was finally applied to vinyl and aryl triflates as substrates.

&81\%
\end{align*}
\]
**d. Conclusion.** Despite the established toxicity of organotins, the Stille reaction remains particularly attractive due to the mild and neutral conditions required for the coupling. There is no doubt that the aforementioned recent techniques will be used to further develop the application of organotins. In addition, the forthcoming efforts to create a real Stille coupling catalytic in tin hold great promise for the future.

**B. Metal Catalysed Coupling Reactions**

1. **Palladium-mediated coupling reactions**

   **a. Carbon–carbon coupling reactions.** There are some reactions involving organotins and palladium catalysis which are not related to the Stille coupling reaction. Whereas the reactivity of organotin was reported as early as 1969 for a Heck-type reaction, the coupling of aryltin with electron-poor olefin or in the presence of a palladium(II) catalyst is quite a recent reaction. Similarly, the difunctionalization of alkenes or alkynes is poorly documented. Interesting results were obtained for the carbostannylation of alkenes by alkynyltin in the presence of an iminophosphine–palladium complex, leading to the corresponding functionalized stannyl enynes (equation 31) in up to 82% yield. Finally, the allylation of pronucleophiles can be achieved as an alternative to the radical or carbanionic processes, with allyltins in the presence of Pd\(_2\)(dba)\(_3\) as a catalyst.

   \text{57%} & \quad (31)
   \end{align*}
   \]

   **b. Carbon–heteroatom coupling reactions.** In addition to the Stille reaction, several carbon–heteroatom coupling reactions can be achieved with organotins and palladium catalysis.

   i. **Carbon–nitrogen bonds.** This reaction was first reported in 1983 by Migita and coworkers, who described the amination of aryl bromides with \(\text{N, N-diethylaminotributyltin}\) (equation 32). The scope of this reaction was studied since 1994 by Hartwig’s and Buchwald’s groups and still represents an advantageous alternative to the classical coupling strategy employing a free amine which necessitates the use of stoichiometric amounts of bases such as NaOBu-t.

   ii. **Carbon–sulfur and carbon–selenium bonds.** The reactivity of the tin–sulfur bond comprises an easy access to aryl,

   heteroaryl, and vinyl sulphides.

   Both unsymmetrical and symmetrical sulphides can be obtained by using trialkyltin sulphides or \(\text{R}_3\text{Sn–S–SnR}_3\) (equation 33). The reaction has been extended to the preparation of alkylaryl selenides with alkylselenotin or PhSeSnBu\(_3\) reagents in up to 88% yield.

   iii. **Carbon–silicon bonds.** Following the earlier reports mentioning the palladium-catalysed addition of organosilylstannanes to alkynes or isonitriles, Mori and coworkers realized tandem transmetallation–cyclization reactions with bifunctional halogeno triflates and Bu\(_3\)SnSiMe\(_3\). The reactivity of 18 under palladium catalysis was used for the silylstannylation of alkenes or the synthesis of allylic silanes via a three-component (aryl iodide + diene + 18) coupling reaction. Recently, a similar
approach to substituted allylic silanes used a three-component coupling reaction involving 18, a substituted allene and various halides as electrophiles (equation 34)\(^4\).

\[
\begin{align*}

\text{Tolune, 100 °C, 3 h} \\
\text{PdCl}_2[\text{P(o-tolyl)}_3]_2 \\
\end{align*}
\]

iv. Carbon–tin bonds. The potential of distannanes to undergo a coupling reaction under palladium catalysis has long been known\(^4\) and represents an easy access to various organotin reagents. Various substrates such as aryl halides\(^4\), aryl acetates\(^4\), vinyl triflates\(^4\), or vinyl chlorides\(^4\) can be used.

2. Copper-mediated coupling reactions

It is established that the addition of copper(I) salts could accelerate the Stille coupling by transmetallating the organotin reagent. Following the pioneering study of Tanaka and coworkers\(^4\), who used the tin-to-copper transmetallation to add various vinyltins to allenes, further work established that the resulting organocopper intermediate could achieve the coupling without any palladium catalysis. Most of the studies were conducted with stoichiometric amounts of copper(I) salts. The air-stable Cu(I)thiophene-2-carboxylate allowed rapid reactions at room temperature between iodides and vinyl or aryltins\(^4\). The reaction was extended to vinylic triflates for the synthesis of cepheums\(^4\). The total synthesis of the sixteen-membered macrolide Elaiolide was achieved via a double coupling reaction (equation 35) as a key step\(^4\). Bis stannyalted compounds undergo five to seven ring closures when subjected to five equivalents of CuCl\(^4\), with yields ranging from 62 to 97%.
Interestingly, it was established that α-substituted organotins were able to couple with electrophiles with catalytic amounts of copper\(^{495,496}\). This exalted reactivity was explained by an intramolecular complexation of the copper atom (equation 36).

Recently, the catalytic use of Cu(I) salts was applied to the aryl–aryl and aryl–vinyl couplings\(^{497}\) and to the allylation of furans and thiophenes\(^{498}\), even without the benefit of such activation. In parallel with the use of Cu(I) salts, the reactivity of stoichiometric amounts of Cu(II) was established for the homocoupling of vinyltins\(^{499,500}\). Copper nitrate was found to be particularly efficient, leading to the cyclotrimerization of 1-bromo-2-stannylalkenes\(^{501,502}\). Lately, the use of catalytic amounts of CuCl\(_2\) was shown to be superior to the use of Cu(I) salts for achieving these homocoupling reactions\(^{503}\).

\[
\text{PMB} = p\text{-MeOC}_6\text{H}_4\text{CH}_2
\]

(Reference 495) (Reference 496)
3. Nickel-mediated coupling reactions

Replacing the palladium catalyst in coupling reactions by a nickel catalyst would broaden the scope of the reaction, since non-activated chlorides would become suitable substrates. However, organotins are much less reactive with such catalysts than their corresponding magnesium or zinc congeners. The first example of nickel-based catalysis concerned the coupling reaction of organic halides with tetramethyltin in the presence of carbon monoxide\(^{504}\). However, synthetic applications dealt essentially with the addition reactions of organotins, such as the addition of alkenyltins to enoxysilanes derived from aldehydes, in the presence of Ni(cod)\(^2\)^{505}. Further extension of this reaction was the Ni(0) catalysed synthesis of stereo-defined enynes by a three-component coupling reaction of alkylnyltins, alkynes and enones (equation 37)^{506}. The reaction is believed to proceed via a \(\eta^3\)-allylnickel complex and was successfully extended to allyl halides as substrates\(^{507,508}\). Other substrates such as aryl mesylates were envisaged, but they lead to the coupling products in only moderate yields\(^{509}\). An intramolecular eight-membered cyclization between an aryl bromide and an aryltin was recently used to prepare the biaryl portion of vancomycin antibiotic\(^{510}\). The corresponding Stille coupling surprisingly failed in that case, and the NiCl\(_2\)(PPh\(_3\))\(_2\) had to be used stoichiometrically in order to raise the yield up to 50%.

![Equation 37]

4. Rhodium-mediated coupling reactions

The use of organotins in conjunction with rhodium catalysis is an emerging reaction which holds great promise due to the potential of these catalysts to activate C—H bonds. For instance, the ortho arylation of 2-arylpuridines has been directly realized with tetraphenyltin in the presence of a rhodium(I)phosphine complex\(^{511}\). A cationic rhodium complex allowed the conjugate addition of arylstannanes to \(\alpha,\beta\)-unsaturated ketones or esters in good yields under neutral conditions\(^{512}\). Finally, alkynylnyltins are able to undergo \([C_2 + C_1 + C_1]\) couplings in the presence of carbon monoxide, giving highly unsaturated cyclobutenone derivatives\(^{513}\).
V. FREE RADICAL REACTIONS

A. Allyltins

1. Background

The radical chemistry of organotins is undoubtedly dominated by tin hydride chemistry, which has been at the source of radical chain reactions of valuable interest for organic synthesis. However, the demonstration of the ability of allyltin reagents to undergo homolytic cleavage of the carbon–tin bond goes back to the early 1970s, and only ten years later Keck and coworkers established the synthetic potential of this reaction. Nowadays this is a particularly useful way of introducing various functionalized allyl groups into a system under mild and neutral conditions.

2. Mechanism and reactivity

The radical chain mechanism involving allytin belongs to the ‘fragmentation method’ family and can be schematically presented as in equation 38, which involves five steps: (i) initiation step, (ii) reaction with the substrate, forming the carbon-centred radical, (iii) a possible evolution of this radical, (iv) addition of the newly formed radical to the allylic double bond and (v) β-scission, regenerating the chain-carrying tin radical.

\[
\begin{align*}
\text{SnBu}_3 & \quad \text{Bu}_3\text{Sn}^- \\
\text{R}^2 & \quad \text{R}^1-\text{X} \\
\text{SnBu}_3 & \quad \text{Bu}_3\text{SnX} \\
\text{SnBu}_3 & \quad \text{SnBu}_3 \\
\end{align*}
\]

The initiation step (i) producing the tributyltin radical can be performed by thermolysis of radical initiators such as AIBN. Complementarily, the use of a Et_3B/O_2 system or of photochemical irradiation allows the reactions to proceed at low temperature. The reaction (ii) with the substrate forming the carbon radical applies the same substrates as those used in tin hydride chemistry, such as iodides, bromides, selenides, xanthates and even thiocarbonates. Furthermore, the possible competitive addition of tributyltin radicals to the allyltin reagent is of no consequence due to the rapid β-fragmentation of the resulting carbon-centred radical, which renders this reaction a degenerate one. It is noteworthy that less reactive radical precursors such as chlorides or phenyl thioethers can be used efficiently. The evolution of the radical (iii) via several intra- or intermolecular elementary
steps before trapping with allyltins is possible, without using any slow addition or high dilution techniques. Indeed, the main difference from tin hydride chemistry lies in the fact that the addition of radicals to the allyltin reagent (iv) is not so fast\(^{524}\) \((k_{\text{add}}\) being only \(10^4-10^5\text{M}^{-1}\text{s}^{-1}\) at 60°C), avoiding a premature quenching of the carbon radicals. This can be illustrated by various three-component intermolecular coupling reactions, involving activated olefins\(^ {525,526}\), or carbon monoxide (equation 39)\(^ {527}\). It is important to note that the electrophillic radicals attack the allyltin \(\pi\) bond more easily than do nucleophilic alkyl radicals\(^ {528}\), whereas the addition of carbon radicals to allyltin is not severely affected by their nature, thus enabling a wide range of substrates to react. For instance, \(N\)-acyl radicals are able to add efficiently to allyltin before their decarbonylation\(^ {529}\). Finally, a rapid \(\beta\)-scission (v) with a rate constant likely over \(10^6\text{s}^{-1}\) occurs to regenerate the tributyltin radical. The efficiency of that step avoids the undesired addition of 19 to the precursor allyltin.

The allylic radical transfer has been applied to the synthesis of complex structures such as \(\beta\)-lactams\(^ {530,531}\), steroids\(^ {532}\), alkaloids\(^ {533}\) or C-glycosides\(^ {534,535}\).

3. Functionalized allyltins

The synthesis and use of functionalized allyltins has been thoroughly explored, especially when functionalized at \(\beta\)-position. The use of allyltins \(\beta\)-substituted by an electron-withdrawing group represents a particularly attractive option, due to their enhanced reactivity towards nucleophilic carbon radicals. For that purpose several allyltins substituted with amide or ester\(^ {536}\), chloride or nitrile\(^ {537,538}\), trimethylsilyl\(^ {539}\) and sulphones\(^ {540}\) as substituents were prepared. They have been used for the synthesis of 1,4-dienes\(^ {541}\), and in amino acids\(^ {542}\) or carbohydrate chemistry\(^ {543}\). The ester functionality may be used afterwards for intramolecular endo-cyclizations leading to 10–15-membered \(\alpha\)-methylene lactones\(^ {544}\). The functionalization by non-activating alkyl groups, such as methyl or hydroxymethyl, is tolerated and more complex organotin reagents, such as 20, were used in the synthesis of prostaglandins\(^ {545,546}\) (equation 40), and \(\beta\)-lactams\(^ {547}\).

Unfortunately, substitution in the \(\gamma\)-position, such as in crotyltin, led to poorly reactive allyltins, due to the decrease in the addition rate of the radicals to the double bond. It has been established that, generally, the competitive allylic hydrogen abstraction became predominant, destroying the crotyltin reagent\(^ {548}\). The use of \(\gamma\)-substituted allyltins for the photo-induced radical allylation of carbonyl compounds represents an interesting
The limitation can then be overcome as well in intramolecular processes such as 5-exo trig cyclizations (equation 41). In a similar way, Baldwin has shown that the substitution at the $\alpha$-position has to be avoided. In that case the competitive tin radical addition to the double bond is not degenerate and isomerization to the non-reactive $\gamma$-substituted counterpart occurs.

\[ \text{Equation 40} \]

\[ \text{Equation 41} \]

4. **The stereoselective approach**

Albeit radical chemistry was regarded for a long time as being unable to achieve stereoselective reactions, there is growing interest in finding new systems which will enable the radical reactions to proceed with a high level of stereoselectivity. Most of the work done with allyltributyltin is relevant to the 1,2-asymmetric induction. The stereocontrol by an adjacent asymmetric centre, of the addition of the radical to the allyltributyltin, proved to be efficient especially with cyclic systems such as $\gamma$-lactones, either under photochemical or thermal activation. The induction of chirality involving acyclic substrates, for which the control is much less obvious, was explored as well. The elegant
study of Hanessian and coworkers\textsuperscript{554}, in which the intervention of a hydrogen bonding rigidified the structure to give diastereoselectivities up to 98 : 2, should be noted.

Another way to fix the substrate structure was to use bidentate Lewis acids, which enabled work to be conducted under chelation control. The use of MgBr\textsubscript{2} \cdot OEt\textsubscript{2} for the allylation of \(\alpha\)-iodo-\(\beta\)-alkoxyesters at \(-78^\circ\text{C}\) gave diastereoselectivities of over 100 : 1 (equation 42)\textsuperscript{555}. Lanthanide triflates were also used and gave de up to 10 : 1 diastereoselectivities at refluxing dichloromethane\textsuperscript{556}. Importantly, this methodology can be extended to achiral substrates by using chiral Lewis acids, prepared from Zn(OTf)\textsubscript{2} and chiral C\textsubscript{2}-symmetric bis(oxazoline) ligands, reaching up to 90% ee\textsuperscript{557,558}.

In addition to the Lewis acid protocols, the stereo-controlled introduction of the allyl group was studied with various chirality inductors. The allylic substitution was realized with a 1,2-asymmetric induction using substrates possessing chiral sulphoxide moieties\textsuperscript{559}. This strategy can be coupled with the use of Lewis acids to enhance the stereo-selection up to 50 : 1\textsuperscript{560,561}. Similarly, the use of arylurea acting as a protic Lewis acid and complexing the sulphoxide is reported to give stereoselectivities of up to 14 : 1\textsuperscript{562}. The use of chiral auxiliaries such as oxazolidinones was reported to act efficiently when the allylation is performed on the oxazolidinone ring\textsuperscript{563,564}. The selectivity was somewhat lower when the reaction was conducted on the tethering chain of the oxazolidinyl nitrogen, due to the unfavourable position of the radical, which is too far away from the stereogenic centre\textsuperscript{565}. This was overcome by using a Lewis acid in order to proceed under chelation control and the selectivity was raised up to 100 : 1\textsuperscript{566}. A recent example of C-centred radical generated in the \(\alpha\)-position to the nitrogen showed a good diastereoselectivity in the absence of any Lewis acid. The de, up to 98 : 2, remained however strongly dependent on the radical nature\textsuperscript{567}. Other auxiliaries, such as oxazolidines\textsuperscript{568} which were used, were shown to be insensitive to Lewis acid additives.

**B. Other Organotins**

1. **Propargyl- and allenyltins**

Propargyltin was equally found to be efficient for transferring an allene group\textsuperscript{569}. A larger excess of propargyltin is needed, however, due to its isomerization to more stable
allenyl tin under the radical conditions (equation 43). This was used in the synthesis of modified nucleosides. Finally, the use of phenylmenthyl esters as chiral inductors proved its efficiency in the synthesis of various stereo-controlled α-amino acids with allyl-, methallyl-, crotyl-, propargyl- and allenyltins. Nevertheless, regarding the unconventional outcome of the reaction, it is not clear if the mechanism is a radical chain process.

\[ \begin{align*}
\text{NHCO}_2\text{Bu}^- & \quad \text{PMBO}_2\text{C} \\
\text{SnMe}_3 & \quad \text{SO}_2\text{Ph}
\end{align*} \]

2. Vinyltins

Vinyltins were used for synthetic purposes in radical addition–elimination sequences. The main limitation comes from the necessity to functionalize the olefin by groups such as esters able to stabilize the transient carbon-centred radical. Phenyl-substituted systems proved to be reactive as well, whereas methyl- and cyclohexenyl-substituted ones failed to react. An intramolecular version was developed giving access to methylene cyclopentane units (equation 44).
3. Miscellaneous

In addition to the use of Bu$_6$Sn$_2$ as initiator for radical reactions, this reagent can be used stoichiometrically to ensure that reactions take place whenever classical organotins failed to react. For instance, it was described that an association of Bu$_6$Sn$_2$ and $\gamma$-substituted allyl sulphides were able to give allylation reactions (equation 45) whereas the corresponding $\gamma$-substituted allyltins were inefficient. Other reagents such as 2,4-pentadienylin were shown to be reactive. In some case alkyltins can participate in radical chemistry when the $\beta$-elimination is thermodynamically favoured, leading for instance to carbocyclic ring expansions. In a similar way radical reactions involving a 1,3-stannyl shift could afford 5-exo cyclizations.

C. New Trends in Allyltin Transfer

Most of the radical reactions are conducted with an excess of the allyltin reagent, so that problems of purification may arise from and combine with the established toxicity of triorganotin side products. This represents the main drawback of the radical organotin methodology. In addition to the development of efficient purification processes, different ways of circumventing these problems are being continuously studied and can be divided into three different classes: (i) the search for catalytic systems which will regenerate in situ the organotin, (ii) the design of new organotin reagents, supported on polymers or leading to easily removable side products and (iii) the invention of alternative free organotin radical systems. The essential part of this work has so far been devoted to optimizing or replacing the tin-hydride chemistry, and very little attention has been paid to the allyl transfer process.

A silicon-based approach, in which various allyltris(trimethylsilyl)silanes were prepared and used for radical allylic transfer, was published, but in contrast to its silicon hydride homologues, these reagents exhibited too much sensitivity towards polar effects which required an adaptation of the nature of the substrate with the allylic moieties, and consequently restricted the scope of their use. Such restrictions are often encountered with all the ‘tin-free’ radical allylation methods in the recent literature. Recently, a new allyloganotin, bearing a ‘polar tail’ to allow an easy purification step, was described. For the same purpose an alternative, using monoallyltin, which gives after hydrolysis of the reaction mixture, inorganic tin side products, was developed. In contrast with electrophilic SnX$_3^*$ radicals, they were able to transfer efficiently the functionalized allyl group via a radical chain mechanism using XSn[N(TMS)$_2$]$_2$ as a chain carrier agent. Allyltin reagents supported on polymer underwent free radical allylic transfer with a marked preference for electron-poor carbon radicals. The fluorous method developed by Curran and coworkers has recently been successfully extended to four-component radical reactions using fluorinated allyltin reagents.

\[ \quad \text{60\%} \]
VI. TRANSMETALLATION REACTIONS

A. Historical Background and General Features

The transmetallation reaction consists of the replacement of the tin atom by another metal and was discovered by Seyferth and Weiner in 1959\textsuperscript{600,601}. In fact, it has already been dealt with in this chapter in connection with some aspects of the transmetallation process: for instance, the activation of allyltins by Lewis acids (Ti, Al, In) for the nucleophilic addition reaction, or some coupling reactions mediated by copper are also relevant to the subject. The favourable driving force renders this reaction general with lithium as a metal and popularized it for various uses in organic synthesis. Indeed, the reactivity of the tin–carbon bond, which is compatible with a high level of functionality, makes organotins much better candidates than organosilicon reagents for this reaction. Other metals, such as copper or boron, were employed later in similar reactions.

B. Tin to Lithium Exchange

1. Alkenyltins

The main feature of tin to lithium exchange is the preservation of the alkene stereochemistry, which was already demonstrated in 1964\textsuperscript{602}. In conjunction with the easy access to stereodefined alkenyltins, this feature has been extensively exploited for synthetic purposes such as the construction of prostaglandins side chains\textsuperscript{603,604} and unsaturated fatty acids\textsuperscript{605,606}, the syntheses of a macrocyclic lactone\textsuperscript{607}, brefeldin A\textsuperscript{608}, cerulenin and aplasmomycin antibiotics\textsuperscript{609–611}. Furthermore, the reaction is compatible with several functionalities on the alkene moieties like unprotected hydroxy\textsuperscript{612–616}, amino\textsuperscript{617}, or esters groups\textsuperscript{618}. The presence of halides is also tolerated\textsuperscript{619}, leading to bifunctional reagents which are further engaged in various annulation reactions\textsuperscript{620–623}. This strategy was extended to the formation of cyclobutenes with tosylates on the tethering chain of the alkene (equation 46)\textsuperscript{624,625}. It should be noted that the tin–lithium exchange occurs faster than the nucleophilic attack to the carbon bearing the tosylate.

\[ \text{BuLi, THF} \stackrel{-20^\circ C}{\longrightarrow} 0^\circ C \]

\[ \text{Ph} \quad \text{TsO} \quad \text{SnBu}_3 \quad \text{BuLi, THF} \quad \text{Ph} \]

\[ \quad \text{61\%} \]

Cis and trans vinyltins exhibited a dramatic difference in terms of the reactivity of the tin to lithium exchange\textsuperscript{626,627}. This enabled an interesting regioselectivity when the substrate possesses several vinyltins functionalities. Also, 1,1- or 1,2-distannylalkenes were successively lithiated\textsuperscript{628}. Additional effects can intervene in the regiocontrol of the lithiation, such as steric effects which favour the terminal lithiation\textsuperscript{629}, or the stabilization of the lithium species by an intramolecular lithium–oxygen complexation\textsuperscript{630}. An interesting reagent is the 1-stannacyclohexa-2,5-diene \( \text{21} \), which is the formal equivalent of the (Z,Z)-1,5-dilithiated penta-1,4-diene (equation 47)\textsuperscript{631,632}.

\[ \begin{array}{c}
\text{Sn} \\
\text{(21)}
\end{array} \]
The reaction was extended to 1,3-dienyltins, giving the corresponding lithiated reagents, both in terminal\textsuperscript{633–635} or internal\textsuperscript{636} position, which can be substituted by alkoxy groups\textsuperscript{637}. Recently, a 1,3,5-triienyl lithium carbanion was prepared in a similar way from 22 and used for a further synthesis (equation 48)\textsuperscript{638}.

2. $\alpha$-Heterosubstituted organotins

The importance of carbanions $\alpha$-substituted by heteroatoms in organic synthesis explains the vast amount of literature concerning the use of $\alpha$-heterosubstituted organotins in transmetallation reactions. As the tin–lithium exchange is assumed to occur with a complete retention of configuration at the carbanion centre\textsuperscript{639}, the enantioselective approach of such stabilized carbanions for synthesis has been the subject of recent developments.

a. Oxygen-substituted organotins. A general route to alkyl-ox-, aryloxy- and allyloxy-methyltins and their subsequent transformation into their lithiated equivalents was proposed more than twenty years ago\textsuperscript{640,641} and is still used for the total synthesis of
complex targets such as Taxusin or aspidospermin alkaloids. The allyloxymethyl lithium intermediate can either react intermolecularly with an appropriate substrate or intramolecularly by way of a [2,3]-sigmatropic rearrangement (equation 49) which has been exploited for numerous syntheses of natural products.

\[
\text{OH} \quad \text{1. KH, THF, 18-Cr-6} \quad \text{2. Bu}_3\text{SnCH}_2\text{I} \quad \text{3. BuLi} \quad \text{OBn} \\
\] \\
\text{75%}

(49)

The extension of the reaction to the preparation of an $\alpha$-substituted alkoxymethyl lithium holds great promise in terms of chirality induction and was investigated by Still already in 1978. The advantage lies in the stabilization of the carbanion formed by the oxygen atom, but it is known that substitution at the carbon bearing the tin atom may render the exchange by the lithium more difficult. This was overcome by changing the aryl tributyltins to more activated trimethyltin reagents, and by conducting the reactions in DME as solvent instead of in THF.

b. Nitrogen-substituted organotins. The preparation of aminomethyllithium species proved its efficiency for the preparation of $\beta$-aminoalcohols a long time ago. However, these reagents remained much less developed till recently, presumably due to their lower configurational stability compared to the alkoxymethyllithium equivalents. Nevertheless, intramolecular ring closures leading to substituted pyrrolidines or azabicyclic structures were achieved. Alternatively, the generation of 2-azaallyl anions by tin–lithium exchange of stannylated imines led to the formation of pyrrolines and bridged azabicyclic compounds by a [3 + 2] cycloaddition approach (equation 50).

\[
\text{SnBu}_3 \quad \text{R}^1 \quad \text{X} \quad \text{R}_2 \quad \text{R}_3 \quad \text{Li} \quad \text{R}_2 \quad \text{R}_3 \quad \text{X} \quad \text{R}_1 \quad \text{Li} \\
\] \\
\text{(50)}

An interesting application concerns the generation of carbanions bearing chiral auxiliaries tethered to the nitrogen. In this case, a rapid equilibration follows the transmetallation step, so that the formation of the more stable aminomethyllithium intermediate is ensured, depending on the stereochemistry of the auxiliary. It then appears possible to take advantage of the configurational instability of the aminomethyl lithium to prepare stereo-defined organolithium and organocopper reagents starting from racemic organotin compounds.
c. Sulphur-substituted organotins. $\alpha$-Thioalkoxymethyl lithiums are readily prepared from the corresponding thiomethyl ethers. Their configurational instability causes a rapid racemization even at low temperature, but the tin to lithium exchange may occur with retention of configuration when starting from some $\alpha$-arylthioalkyltins and $\alpha$-arylthioalkenyltins. Further transmetallation from lithium to zinc was also exemplified. Recently, the tin to lithium exchange, in the presence of the chiral bis (oxazoline) bidentate ligand to complex the transient organolithium followed by trapping with a carbonyl compound as an electrophile furnished the thioalcohol with a high level of enantioselectivity. Interestingly, lithiated carbanions prepared from $\alpha$-arylthioalkyltins appeared to undergo carbon–carbon bond fragmentation as well when a carbonyl group was suitably placed in the $\gamma$-position.

\[ \text{Ph} \text{S} \text{SnBu}_3 \xrightarrow{n-\text{BuLi}} \text{Ph} \text{S} \text{Li} \]

(51)

3. Other organotins

The organotins mentioned below are used much less for generating organolithium reagents, because there are alternative procedures which can efficiently replace the tin–lithium exchange reactions. Allyltins were the first organotins to be transmetallated, and the methodology was rapidly extended to related compounds such as methallyl, crotyl, and prenyltins. With such reagents, a competition between the $\alpha$- and $\gamma$-reaction sites of the lithiated intermediate may occur. It should be kept in mind that the nature of the substituents may affect the regiochemistry either by steric or by electronic effects. In some cases the addition of $\text{Ti(OPr-i)}_4$ prior to the addition of the electrophile may reverse the regioselectivity. Nevertheless, the transmetallation of allyltins for synthetic purposes has scarcely been used, due (i) to the sufficient reactivity of the allyltin itself and (ii) to the easy preparation of allyllithium by the deprotonation method. For the same reasons there are very few examples of transmetallation with benzyltins, although this reaction is easily carried out. Although the tin–lithium
exchange is assumed to be easier than the bromine–lithium exchange, aryl and heteroaryltins are rarely used due to the fact that the corresponding lithiated reagents are commonly prepared by deprotonation reactions or by halogen–lithium exchange reactions.

The applications of tin to lithium transmetallation involving alkyltins remain uncommon, with the exception of cyclopropyllithium reagents. They were primarily used by Corey and coworkers for the synthesis of hybridolactone with a total retention of configuration at the carbon bearing the metal. This stereoselectivity was further investigated and shown to be unaffected by the functionalization of the cyclopropyl moiety. Recent results on dichlorodialkyltin showed a marked contrast in its reactivity compared with the parent teraalkyltin (equation 52). This was explained by an intramolecular complexation of the tin atom, which is responsible for the activation of and predisposes the system to obtain selectively the Z-form enolate. Finally, we note the synthesis of fluoroolefins via the transmetallation of a bis(trimethylsilyl)fluoromethyltin reagent, followed by the addition of the resulting organolithium to carbonyl compounds.

\text{t-Bu} \\
90\% \quad E/Z = 0/100
\]

C. Other Transmetallations

1. Tin to copper exchange

Although there were numerous examples in the literature of tin to copper transmetallations, the exchange reactions involved a transient organolithium until recently. There is no doubt that, during the last decade, the main advance for organic synthesis in tin–metal exchange reactions is related to the tin to copper direct transmetallation. The first example, reported by Behling and coworkers in 1988, was the formation of mixed cuprate upon treatment of an alkenytin with \( R_2\text{Cu(CN)}\text{Li}_2 \) without prior lithiation. The reaction was shown to be general with alkenyltins, and was readily extended to the formation of allylic cuprates.

The reaction was applied to the formation of arylcopper used for homocoupling and coupling reactions, which have already been described in Section IV.B.2. In addition, it was established that the simple use of copper(I) salts in polar solvents permitted the transmetallation from tin to copper. The transient vinylcopper reagent was subjected to various intramolecular reactions such as coupling with vinyl halides, addition to \( \alpha, \beta \)-unsaturated ketones, to \( \alpha, \beta \)-unsaturated esters and addition to \( \alpha, \beta \)-alkynic esters. In addition to copper(I) halides, the reaction can be mediated by copper(I) cyanide and
applied to the synthesis of fused bi- and tricyclic structures (equation 53).

2. Tin to boron exchange

The transmetallation process was extended to the preparation of vinylboranes, and the superior reactivity of organotins over organosilicons was elegantly demonstrated by Williams and coworkers for the preparation of the optically active allylborane from the corresponding allylic stannane in the total synthesis of \((-\)-Hennoxazole A \(^{\text{711}}\) (equation 54).
VII. SUBSTITUTION REACTIONS

A. Halodestannylations

1. Introduction

The halodestannylation of organotins is a long-known reaction established for vinyltins by Seyferth in 1957\(^ {712} \). The reaction has been widely applied to aryl-, heteroaryl- and vinyltins, and to a lesser extent to benzyl- and allyltins. Its popularity is due to the easy cleavage of the tin–carbon bond in reactions with electrophiles, which allows a great reactivity, and a high level of chemo- and regioselectivity, under particularly smooth conditions. The reactivity in the Sn–C halodestannylation follows the following order: Ph > PhCH\(_2\) > CH\(_2\)=CH > Me > Alk. A striking application of the halodestannylation reaction is represented by the widening use of organotin precursors for the synthesis of labelled bioactive molecules used as radiotracers in nuclear medicine.

2. Iododestannylation

The iododestannylation reaction is a commonly used reaction due to the high reactivity of the formed vinyl iodides, which can be used for further transformations. The stannylated precursors are easily prepared by hydrostannation of alkynes, and the iodide–tin exchange proceeds with an excellent regio- and stereocontrol. Furthermore, the reaction is compatible with the presence of several functionalities such as ethers\(^ {713,714} \), alcohols\(^ {715–718} \), ketones\(^ {719,720} \), esters\(^ {721,722} \) and amines\(^ {723} \). Functionalized dienyltins were also used for the preparation of 1-iodo-1,3-dienes\(^ {724} \), and the reaction was even extended to the preparation of fully stereo-determined iodo tetraenes\(^ {725} \).

Aryl- and heteroaryltins\(^ {726,727} \) are similarly used for the synthesis of the corresponding iodides, and they also allow the presence of functional groups such as alcohols\(^ {728} \), esters and amides\(^ {729} \) and amines\(^ {730} \). It is noteworthy that with substrates such as allyltins or propargyltins the iododestannylation occurs with rearrangement of the unsaturation\(^ {731,732} \).

The main application of this reaction in the last twenty years is undoubtedly the preparation of various radiotracers labelled with iodide 131, 125 or 123 (I\(^ * \)) for SPECT medical imaging. For such radiosynthesis, NaI\(^ * \) associated to an oxidant is preferred over the usual I\(_2\)-mediated iododestannylation. Among several examples of bioactive molecules synthesized in recent years, the iodopyridine\(^ {25} \) (a radioligand for nicotinic receptors)\(^ {733} \) or iodopyridine bisphosphonate\(^ {26} \) (a bone disease related tracer)\(^ {734} \) was prepared in high radiochemical yields. Similarly, iodoaromatic derivatives such as 4-iodosipperone\(^ {27} \) (a selective antagonist for 5-HT\(_2\) serotonin receptors)\(^ {735} \), deoxy-nojirimycin derivative\(^ {28} \) (a glucose analog)\(^ {736} \), benzodiazepine\(^ {29} \)\(^ {737} \), the vesamicol analog\(^ {30} \) (an acetylcholine transport inhibitor)\(^ {738} \) or methoxybenzamide\(^ {31} \) (a breast cancer imaging agent)\(^ {739} \) were prepared via the iododestannylation procedure.
In order to facilitate the purification step, organotin precursors supported on polymers were also used for the iododestannylation reaction. The reaction occurred in reasonable reaction times, which are compatible with the use of short half-life radioactive elements, thus allowing the preparation of iodolisuride (a dopamine D2 receptor
imaging agent\textsuperscript{743} or the oestrogenic derivative 33\textsuperscript{744}.

![Chemical structures](image)

3. Bromodestannylation

This reaction can be similarly applied to bromination with \( \text{Br}_2 \textsuperscript{745} \), \( \text{CuBr}_2 \textsuperscript{746} \) or \( \text{BrCN} \textsuperscript{747} \) as the halogenating reagents. Alternatively, in the total synthesis of Calyculin, a vinyl bromide synthon was prepared from the corresponding vinyl stannane by reaction with NBS\textsuperscript{748}. Radiotracers for medical imaging can be synthesized by using short-lived isotopes such as \( ^{75}\text{Br} \left( t_{0.5} = 97 \text{ min} \right) \) or \( ^{76}\text{Br} \left( t_{0.5} = 16.2 \text{ h} \right) \). In addition to the classical NaBr\textsuperscript{–}/oxidant couple, the labelled targets can be prepared with \( \text{NH}_4\text{Br} \) and chloramine-T\textsuperscript{749–751} or peracetic acid\textsuperscript{752} as oxidizing agent.

4. Fluorodestannylation

There are several reagents applicable for the fluorodestannylation. In addition to \( \text{F}_2 \textsuperscript{753,754} \) and acetyl hypofluorite\textsuperscript{755}, xenon difluoride\textsuperscript{756} was able to replace the organotin moiety by a fluorine under mild conditions. In the same way caesium fluorooxysulphate is able to give an electrophilic fluorination on aryltins\textsuperscript{757} as well as on alkenyl- and heteroaryltins\textsuperscript{758}. Finally, the difluorotriphenylstannate\textsuperscript{759} has to be mentioned, although it is not relevant to the fluorodestannylation. This hypervalent tin reagent is an anhydrous nucleophilic fluorinating agent for benzylic and aliphatic substrates\textsuperscript{760}. The radiosyntheses of bioactive molecules were achieved with sources of \( ^{18}\text{F} \left( t_{0.5} = 120 \text{ min} \right) \)\textsuperscript{761–763}.

B. Tin to Oxygen Substitution

Benzy1- and allyltins possess a relatively weak tin–carbon bond enabling an easy oxidation with \( m \)-chloroperbenzoic acid. The corresponding alcohols are obtained\textsuperscript{764,765} with rearrangement in the particular case of allyltins\textsuperscript{766}. The oxidation of vinyltins by \( m \)-chloroperbenzoic acid (MCPBA) gives the corresponding epoxide\textsuperscript{767,768}. Interestingly, the oxidation of vinyltins by lead tetraacetate does not follow the same route and gives the corresponding alkyne\textsuperscript{769,770}.

With non-activated tin–carbon bonds such as allyltins, strong oxidizing agents like chromium trioxide are usually required\textsuperscript{771}. The reactions lead to the corresponding alcohols or ketones, depending on the substitution of the carbon bonded to the tin atom.
Iodosylbenzene can oxidize the tin–carbon bond as well. This reaction is followed by a stereospecific ring opening when operating with γ-stannyl cycloalkanols. An m-chloroperbenzoic acid may be used, giving selectively the alcohols with retention of configuration. A two-step procedure involving the initial cleavage of an alkyl substituent by bromine, followed by an oxidation of the resulting trialkyltin halides with ammoniacal MCPBA was described. An alternative method using ceric ammonium nitrate was also developed to transform selectively primary alkyltins into aldehydes and applied to the total synthesis of the antibiotic Burseran. Recently, fluorinated organotins were subjected to a mild oxidation system (alkaline H₂O₂) giving the alcohols with retention of configuration (equation 55).

\[ \text{SnBu}_2(Rf) \rightarrow \text{MeOH/THF, 14 h} \rightarrow \text{H}_2\text{O}_2/\text{KHCO}_3 \rightarrow \text{alcohols, 73%} \] (55)

C. Tin to Sulphur Substitution

Sulphonyl chloride reacts with aryl- and vinyltins to give the corresponding sulphones. In conjunction with secondary amines, the reaction with sulphonyl chloride gives access to sulphonamides. In addition, the reaction of aryltins with arenésulphonyl halides gives the dissymmetric sulphones. Dithiocyanogen reacts as well with aryl-, vinyl- and allyltins to form the thiocyanates. When different types of tin–carbon bonds are present, the reaction is chemoselective showing the following selectivity order: benzyl > aryl > alkyl.

I. INTRODUCTION

The chemistry of $R_3 MH$ ($M = \text{Ge, Sn, Pb}$) is highlighted firstly by the dominance of trialkyltin hydrides in synthesis, and secondly by the prevalence of free-radical chemistry in the large majority of transformations of synthetic significance reported in the literature.
There is no doubt that free-radical chemistry has benefited enormously through the invention of tin-based chain-carrying reagents\textsuperscript{1–5}. Of these, tributyltin hydride and, to a lesser extent, triphenyltin hydride have been the reagents of choice\textsuperscript{1}. Their ready availability and favourable rate constants for attack of the corresponding tin-centred radicals at a variety of radical precursors\textsuperscript{6}, coupled with useful rate constants for hydrogen transfer\textsuperscript{7} to alkyl and other radicals, provide for reagents superior to their silicon counterparts\textsuperscript{8}; only tris(trimethylsilyl)silane rivals tributyltin hydride in its synthetic utility\textsuperscript{9}.

A knowledge of rate constants is crucial to the successful design of synthetic procedures involving these reagents. Giese points out that stannane chain-carrying reagents are useful because a knowledge of the important rate constants allow, through control of substrate concentration, necessary selectivity criteria to be met\textsuperscript{1}.

Toxicity\textsuperscript{10} and product purification\textsuperscript{11} concerns have led to the development of ‘friendlier’ reagents. Improvements in synthetic flexibility resulting from the use of germanes as hydrogen donors has resulted in extensions of free-radical methodology to systems in which the primary bond-forming reaction (e.g. intramolecular addition) lies outside the range acceptable for stannane chemistry\textsuperscript{1}. The use of trialkylgermanes, for example, with their lower rate constants for the delivery of hydrogen atom to alkyl radicals can often lead to increased reaction yields when slow C–C bond-forming reactions are crucial in the overall synthetic strategy\textsuperscript{12–14}.

Hydrostannylation represents another class of important reaction that often gives rise to interesting polymeric materials as well as precursors for transition metal mediated coupling transformations such as the Stille coupling protocol\textsuperscript{15}.

Davies provides a comprehensive account of the state of organotin hydride chemistry up to the end of 1995 in his recent book\textsuperscript{15}, while Gielen and coworkers detail methods for the preparation of organo-germanium, tin and lead compounds in their 1995 contribution to this series\textsuperscript{16}; the reader is referred to these works for chemistry which precedes that found in this chapter. The purpose of this account is to consolidate developments since the work of Davies and Gielen. Consequently, the preparation and synthetic uses of R\textsubscript{3}MH (M = Ge, Sn, Pb) from the beginning of 1996 until the end of 2000 are documented in this chapter.

New methods for the preparation of germanes and stannanes reported since 1995 are dealt with in Section II. In Section III, radical chain chemistry involving trialkyltin hydrides is examined. In particular, the synthetic utility of tributyltin hydride will be reviewed, as well as that of other stannanes. Recent advances in the area of asymmetric radical chemistry involving chiral non-racemic stannanes are also included. Section IV details a limited number of examples of non-radical stannane chemistry, while Section V covers recent advances in germane and plumbane chemistry. While we have restricted ourselves largely to the literature since the beginning of 1996, some salient features of earlier work are included when relevant to the discussion.

II. THE PREPARATION OF NOVEL TRIALKYLMERMANES AND STANNANES

A. Trialkygermanium Hydrides (R\textsubscript{3}\text{Ge}H)

Work describing procedures for the preparation of trialkygermanium and tin hydrides is well documented\textsuperscript{16}. Since 1996, to the best of our knowledge, there have appeared few papers detailing novel preparations or methods for the preparation of new trialkygermanium hydrides. Of those few, Colacot describes a one-pot preparation of tributylgermanium hydride by reaction of GeCl\textsubscript{4} with butyllithium chloride in the presence of a catalytic amount of titanocene dichloride (equation 1)\textsuperscript{17}, while Takeuchi and his colleagues report the synthesis of tris[2-alkoxyphenyl]germanes (1) and
related compounds by standard methods (equation 2\textsuperscript{18}). Oshima and coworkers report the preparation of tri-2-furanylgermane (2) by reaction of 2-furanyl lithium with GeCl\textsubscript{4} followed by lithium metal (equation 3\textsuperscript{19}), while Tacke and coworkers describe methods for the synthesis and enzymatic separation (porcine pancreas lipase, PPL) of chiral germanes (3) (equation 4\textsuperscript{20,21}).

Esteruelas and his associates report the preparation of OsH(\eta^5-C_5H_5)Cl(GeHPH_2)(i-Pr_3P) (4) by treatment of 5 with Ph_2GeH_2 and describe interesting exchange
chemistry en route to 5 (equation 5)\textsuperscript{22}. Jutzi and coworkers describe the conversion of bis(2,4,6-tri-tert-butyl)germylene, a \(-30^\circ\text{C}\) stable orange-red crystalline solid, into germaindane (6) through the use of Lewis acid catalysed C–H bond insertion chemistry (equation 6)\textsuperscript{23}. Unno and coworkers describe the preparation and reactions of hepta-tert-butylcyclotetragermane (7) which is conveniently prepared by the reductive coupling of 1,2-dichloro-1,1,2,2-tetra-tert-butylgermane (equation 7)\textsuperscript{24}.

Polymer-supported germanium hydrides have been investigated by Mochida and co-workers who report the preparation of poly(4-diethylhydrogermane)styrene and related polymers and examine their reactivity as free-radical reducing agents (equation 8)\(^\text{25}\).

Very recently, Gualtieri reported the preparation of chiral, \(C_2\)-symmetric binaphthyl-substituted germanes (8, 9) containing \(S\--\text{Ge}\) bonds (equation 9) and their application to enantioselective radical chemistry\(^\text{26}\). These compounds are reported to exhibit superior stability properties than the corresponding tin compounds which could not be isolated (see later)\(^\text{26}\).

**B. Trialkyltin Hydrides (\(R_3\text{SnH}\))**

The past five years have witnessed several advances in stannane technology with direct application to organic synthesis. Significantly, the introduction of fluororous
reagents, chiral, non-racemic stannanes and the development of more robust polymer-supported tin hydrides will be seen in the future as major advances with direct application to many areas of synthesis, including the regulation-intensive pharmaceutical industry.

In a series of papers, Curran and coworkers introduce several fluorous stannanes with distinct separation (extraction and chromatography) and combinatorial chemistry advantages over traditional trialkyltin hydrides. These perfluorinated stannanes (10) are conveniently prepared by the reaction of the appropriate fluorous Grignard reagent with phenyltrichlorotin followed by standard manipulation (equation 10)\(^{27-30}\) and have the advantage of having limited solubility, depending on fluorine content, in both organic and aqueous media. Purification can often be facilitated by extraction of the fluorinated tin by-products into a fluorous solvent in which the reaction products are insoluble.

\]

\(\text{Rf} = \text{C}_4\text{F}_9, \text{C}_6\text{F}_{13}, \text{C}_{10}\text{F}_{21}, n = 2,3\) (10)

Enantioselective free-radical chemistry has benefited through the development of chiral, non-racemic stannanes. Despite having been prepared on a limited number of occasions prior to 1996, the use of chiral stannanes in enantioselective free-radical chemistry was only reported on one occasion\(^{31}\). The field effectively lay dormant until Nanni and Curran reported the preparation and uses of (S)-4,5-dihydro-4-methyl-3H-dinaphtho[2,1-c:1′,2′-e]stannepin (11) prepared from (S)-2,2′-bis(bromomethyl)-1,1′-binaphthyl (equation 11)\(^{32}\) and a few years later Curran and Gualtieri reported the preparation of C\(_2\)-symmetric
Synthetic uses of $R_3MH$ (M = Ge, Sn, Pb)

In the meantime, Vitale and Podestá reported the preparation of mixed alkyldimethyltin hydrides (15)\(^{35}\) from the known bromide (16) (Scheme 2)\(^{36}\), as well as trimehtyltin hydride (17) for structural and ionic-reduction purposes\(^{35,37}\); this work followed on

**SCHEME 1**

In the meantime, Vitale and Podestá reported the preparation of mixed alkyldimethyltin hydrides (15)\(^{35}\) from the known bromide (16) (Scheme 2)\(^{36}\), as well as trimehtyltin hydride (17) for structural and ionic-reduction purposes\(^{35,37}\); this work followed on
from an earlier paper detailing the analogous dialkylmenthyltin hydrides\textsuperscript{38}. These preparations often lead to epimerization at C1 in the menthyl substituent, presumably due to electron-transfer processes\textsuperscript{39}. Dakternieks, Schiesser and coworkers were able to control this epimerization process during the preparation of menthylidiphenyltin hydride (18) and related compounds through the incorporation of a Lewis base during the Grignard chemistry (equation 12)\textsuperscript{39}. These same authors also report the preparation of menthyl-substituted stannanes (19–22) containing intramolecular coordinating substituents (Scheme 3)\textsuperscript{40}, as well as the preparation of some unstable oxazoline-substituted systems (23) (equation 13)\textsuperscript{41}.

The Schiesser group also recently described the preparation of some stannanes (24–27) derived from cholestanol (Scheme 4), cholic acid (Scheme 5) and lithocholic acid (equation 14), and their application to enantioselective radical chemistry.42,43

Tomas and his colleagues employed Diels–Alder methodology to prepare a series of racemic 3-substituted bicyclo[2.2.1]heptan-2-ylstannanes and related compounds (28–31) (Scheme 6).44 The use of optically-pure (R)-4,4-dimethyl-2-oxotetrahydrofuran-3-yl (E)-3-triphenylstannylprop-2-enoate afforded the optically-pure adduct (32) after separation
which was subsequently converted into stannane (28) with 94% enantiomeric excess. Further manipulation gave the chiral, non-racemic tin hydride (29)\(^{45}\). Standard lithiation chemistry has been employed in the preparation the alkyl-substituted systems (33–36)\(^{46}\).

In order to facilitate solid-phase Stille coupling chemistry, Nicolaou and coworkers prepared polystyrene-di-butyltin hydride\textsuperscript{50}. While this polymer has been reported previously\textsuperscript{51}, the preparation on a 2\% cross-linked resin represents a novel extension.
III. TRIALKYL Tin HYDRIDES AS REAGENTS IN RADICAL CHAIN REACTIONS

A. General Aspects

The synthetic application of free-radical reactions has increased dramatically over the past twenty years. Nowadays, radical reactions can often be found driving the key steps of multistep chemical syntheses oriented towards the construction of complex natural products or other synthetic targets. The majority of radical reactions of interest to synthetic chemists are chain processes. Tributyltin hydride is by far the most commonly used reagent for the reduction of functional groups and formation of C−C bonds either inter- or intramolecularly (cyclization), although, as already alluded to, there are several problems associated with organotin compounds. The main drawback consists of the incomplete removal of allegedly toxic tin by-products from the final material.

The transformation of 6-bromo-1-hexene (38) into methylcyclopentane by the action of tributyltin hydride (Scheme 7) typifies the richness of the C−C bond forming chemistry in question. A knowledge of the critical rate constants (\(k_c\), \(k_H\) and \(k_{Br}\) in Scheme 7) allow, through control of substrate concentration, necessary selectivity criteria to be met. Specifically the 5-hexenyl radical (39) must undergo intramolecular addition to form the cyclopentylmethyl radical (40), 40 must abstract a hydrogen atom from tributyltin hydride and the tributylstannyl radical must abstract the halogen in 38 to form 39. These processes must proceed faster than any competing side reaction.

\[
\text{Scheme 7}
\]
B. Tributyltin, Trimethyltin and Triphenyltin Hydride (Bu₃SnH, Me₃SnH, Ph₃SnH)

The number of publications in the period of coverage of this chapter detailing the use of Bu₃SnH, Me₃SnH or Ph₃SnH in synthesis, either in direct reduction chemistry, or in multi-step transformations, is truly remarkable. Indeed, it is not practical for all examples to be included in this account. It is our intention, therefore, to present a comprehensive description of the diversity of the chemistry in question through the use of numerous selected examples, while the entire list of references is included for completeness.

1. Free-radical reduction chemistry

During the period 1996–2000 the use of Bu₃SnH, Ph₃SnH or Me₃SnH in simple free-radical reduction chemistry of halides was reported on numerous occasions. The versatility of these stannane reagents lies in their ability to reduce a variety of other common functional groups that act as radical precursors. These include sulphides, selenides, tellurides, thiono- and dithiocarbonates, selenoesters, nitro compounds, sulphoxide, sulphate and sulphonyl moieties, as well as other functionalities.

Examples of halide reduction chemistry include the Bu₃SnH-mediated reduction of iodide (41) en route to clavepictine A and B reported by Momose and coworkers (equation 17) as well as the reduction of iodide (42) during Danishefsky’s work towards the synthesis of epothilone A (equation 18). Herzog and Roewer demonstrated that trimethyltin hydride can be used to effect the reduction of haloallogilanes to the corresponding silane in the presence of a Lewis base such as triphenylphosphine (equation 19), while Crich and Mo reported the beneficial effect of catalytic benzeneselenol during the Bu₃SnH-mediated reduction and fragmentation of bromo-β-lactones (43) (equation 20).

(17)
19. Synthetic uses of $R_3MH$ ($M = \text{Ge, Sn, Pb}$)

Hoshino and coworkers describe the synthesis of (S)-(+)-α-methoxymethylhydrocoumarin through the Bu$_3$SnH-mediated enantioselective reduction of iodide (44) in the presence of a chiral Lewis acid (equation 21)$^{100}$. On a similar theme, Guindon and Rancourt reported chelation-controlled diastereoselective radical reductions utilising Bu$_3$SnH in the presence of magnesium salts, an example of which is given in equation 22$^{109}$. It is interesting to note that while the syn product dominates in the presence of MgI$_2$, it is the anti product which is preferred in the absence of Lewis acid.
Lange and his associates reported the reductive ring expansion of the tricyclic iodide (45) during the synthesis of some terpene natural products (equation 23)\textsuperscript{125}. It is interesting to note that the stannane reacts exclusively with the iodide moiety in this transformation, with the xanthate functionality providing the final $\beta$-scission that completes the radical chain process. Banwell and coworkers described the Bu$_3$SnH-mediated removal of a bridgehead bromide in their synthesis of a highly-functionalised steroidal nucleus (equation 24)\textsuperscript{127}.

Roush and Bennett reported the consecutive removal of seven iodine atoms during their synthesis of the landomycin A hexasaccharide unit (46) (equation (25))\textsuperscript{151}. 

\[
\text{Bu}_3\text{SnH} / \text{Et}_3\text{B} \quad \text{MgI}_2 \text{ or no additive} \quad \text{Bu}_3\text{SnH} / \text{Et}_3\text{B}
\]

\[
\text{syn:anti} = 84:1 \quad R^1 = \text{Ph}, \quad R^2 = \text{i-Pr (MgI}_2) \quad 1:13 \quad \text{(no additive)}
\]
Sulphides can often be problematic as free-radical precursors mainly because of their reduced rate of reactivity towards tributyltin radicals when compared to bromides, iodides or selenides. However, several examples exist in which sulphides have effectively been reduced using tin hydrides. For example, Quiclet–Sire and coworkers reported the removal of the thiopyridyl moiety from the product of a Barton ester reaction using Bu$_3$SnH (equation 26). Beckwith and Duggan investigated the quasi-homo-anomeric interaction in some substituted tetrahydropyranyl radicals by careful analysis of the products of Bu$_3$SnD reduction of selected $p$-tolylthio precursors. Hoppe and coworkers described the removal of the thiophenyl moiety in substrate (47) (equation 27). Rigby and Laurent reported the selective reduction of one of the sulphide groups in several geminal sulphides (e.g. 48) during their synthetic studies (equation 28). Presumably, this transformation is the result of the activation of the sulphide undergoing reduction by the other sulphur on the same carbon.
Selenides are more effectively removed by the action of trialkylstannanes. For example, Jung and Xu reported the Bu₃SnH reduction of phenylselenide (49) during their preparation of L-2-deoxyribose from D-ribose (equation 29)¹⁸². This reaction proceeds with apparent benzoyl group migration and has been reported previously by Giese and coworkers³²⁰. Stojanovic and Renaud showed that tosylated N,Se-acetals (50) often undergo β-scission during reaction with Bu₃SnH under standard reaction conditions (equation 30)¹⁸⁶, while Pearson and Stevens utilised Bu₃SnH-mediated reduction of phenylselenide (51) in their preparation of tropane alkaloid analogues (equation 31)¹⁸⁹.

Danishefsky and coworkers showed that selenide (52) undergoes reduction upon treatment with Bu₃SnH in the presence of allyltributyltin, rather than allylation, as expected (equation 32)¹⁹⁷. In this last example, Uriel and Santoyo-González utilised Bu₃SnH reduction of a glycosidic phenyl selenide (53) in their synthesis of 2-deoxyglycopyranoyl thioureas (Scheme 8)¹⁵⁹. This example typifies the synthetic utility of phenyl selenides,
which are incorporated readily using standard chemistry that also often incorporates other functional groups.

\]

(32)

During the period covered by this chapter, there appears to have been only one report of the reduction of a telluride; Ferraz, Sano and Scalfo described the routine reduction of a phenyltelluride using \text{Bu}_3\text{SnH}\text{.}^{201}

Thiono-, dithiocarbonates (xanthates) and related compounds often provide effective routes for the removal of unwanted oxygenation, especially secondary alcohols, through the Barton–McCombie reaction\textsuperscript{202}. For example, Font and his associates utilised this chemistry en route to grandisol in which the fluorophenylthionocarbonate (54) was reduced using tributyltin hydride under standard radical conditions (equation 33)\textsuperscript{210}. In this example the by-product (55) is also formed, presumably a result of the release of strain associated with the four-membered ring. White and Jeffrey described the \text{Bu}_3\text{SnH}-mediated reduction of xanthate (56) during their synthesis of the tricarbonyl subunit of rapamycin (equation 34)\textsuperscript{212}, while Schintzer and Ringe utilize a similar strategy in their syntheses of \(\beta\)-pinguisene (57) and \(\beta\)-pinguisenol (equation 35)\textsuperscript{214}.

(35) $\xrightarrow{\text{Bu}_3\text{SnH} / \text{AIBN}}$ (57)
Gössinger and coworkers reported the Bu$_3$SnH-mediated reduction of xanthate (58) in their work towards the synthesis of nodusmicin (equation 36)\textsuperscript{220}. Cornforth, Hanson and their associates investigated the unusual generation of methoxy groups during the reduction of xanthates (59) derived from lanosterol (equation 37) and proposed a mechanism to account for this observation\textsuperscript{222}. It should be noted that this transformation afforded primarily the expected deoxygenated product, with the methyl ether representing only 14% of the reaction mixture.
Zoretic and coworkers described the stannane-mediated deoxygenation of 60 as part of their synthesis of \( d,l \)-norlabdane oxide (61) and related odorants (equation 38)\(^{232}\). Martin and coworkers employed stannane-mediated deoxygenation of substrate (62) as part of their strategy for the synthesis of a segment of herbimycin A (equation 39)\(^{252}\). Camps and his associates reported the \( \text{Bu}_3\text{SnH} \)-mediated deoxygenation of the thiocarbonyl imidazolide (63) during their synthesis of analogues (e.g., 64) of huperon A (equation 40)\(^{258}\). Tachibana and coworkers described a convergent synthesis of a decacyclic ciguatoxin model in which a key step involved the removal of the thionocarbonate moiety in 65 by the application of \( \text{Bu}_3\text{SnH} \) (equation 41)\(^{262}\).

\[
\begin{align*}
\text{Bu}_3\text{SnH} &\quad \text{Pd-C} \\
\text{H}_2 &\quad \text{AIBN}
\end{align*}
\]
Hu, Sun and Scott described recently an efficient synthesis of some taxadiene derivatives\(^{266}\). In their approach, alcohol (66) is treated with carbon disulphide followed by methyl iodide under standard conditions for the formation of xanthates, to afford the dithiocarbonate (67) in a process that presumably involved a Claisen rearrangement (Scheme 9). Interestingly, 67 undergoes smooth reaction with Bu\(_3\)SnH to provide the required products (68, 69)\(^{266}\).
Kibayashi and coworkers described the stannane-mediated reduction of xanthate (70) in their work towards the preparation the marine alkaloid (−)-lepadin B (equation 42), while Danishefsky and his associates provide an elegant, fully synthetic route to the neurotrophic tricycloilliconone (71) involving the reduction of xanthate (72) (equation 43).

Selenoesters are effective radical precursors which can afford aldehydes by direct reduction with reagents such as Bu₃SnH, or decarbonylated (nor-aldehyde) products. For example, Stojanovic and Renaud described the decarbonylative reduction of phenylselenoester (73) during their synthetic investigations (equation 44). Similarly, Alcaide and his associates utilised decarbonylative reduction of a phenylselenoester during their
preparation of novel C4-unsubstituted $\beta$-lactams (equation 45)$^{281}$, while Keck and Grier described non-decarbonylative reduction chemistry for $N$-acyl(phenylseleno)oxazolidinones (equation 46)$^{132}$.

Nitro compounds are also able to be reduced by stannanes under free-radical conditions. For example, Kitayama described the reduction of the nitro moiety in 74 by the action of Bu$_3$SnH during his preparation of pheromones for *Bactrocera Nigrotibialis*, *Andrena Wilkella* and *Andrena Haemorrhhoa* (equation 47)$^{282}$. Petrini and coworkers reported the selective reduction of the nitro group in a series of $\omega$, $\omega$-dichloro-$\omega$-alkanoates (75); it is interesting to note that the chlorine atoms remain intact during the reaction with Bu$_3$SnH (equation 48)$^{283}$. Witczak and coworkers described the reduction of substrate (76)
with Bu$_3$SnH en route to $\beta$-(1,4)-3-deoxy-C-disaccharides derived from levoglucosenone (equation 49)$^{285}$. 

Crossley and his associates described new synthetic routes to $\alpha$-amino acids and $\gamma$-oxygenated $\alpha$-amino acids through Bu$_3$SnH-mediated denitration chemistry (equation 50)$^{287}$. Ikeda and his associates reported the stannane-mediated removal
of the nitro functionality in furan (77) in their studies towards the preparation of octahydrobenzo[b]furans (equation 51)\textsuperscript{284}; note the concomitant deconjugation of the double bond in the major product, presumably driven by radical stabilization factors. Uno, Kasahara and Ono denitrated 78 en route to novel α-branched serine derivatives (equation 52)\textsuperscript{289}.

\]

(major product)

(77)

Sulphoxides, sulphates and sulphonyl compounds have also been used as substrates in stannane-mediated reductions. Gethin and Simpkins reported the \text{Bu}_3\text{SnH}-mediated removal of the tosyl group in substrate (79) in their preparation of protected thymine polyoxin C (equation 53)\textsuperscript{293}. Similarly, Xu and Lu described the removal of the tosyl group in 80 under similar conditions during their synthesis of pentabromopseudilin (equation 54)\textsuperscript{294}. Padwa and his associates utilised \text{Bu}_3\text{SnH} to remove the sulphone moiety in cyclopentenone (81) (equation 55)\textsuperscript{295}, while Wnuk and coworkers discuss
the stannyl radical mediated cleavage of π-deficient heterocyclic sulphones during the synthesis of α-fluoro esters (equation 56)\textsuperscript{197}. 

\[ \text{AIBN} \xrightarrow{Bu_3SnH} \text{Bu}_3\text{SnH} \]

(53)

(79)

(54)

(80)

(55)

(81)
During the time frame covered by this chapter, stannanes have been reported to have been involved in radical chemistry not involving the more traditional functionalities. For example, Marzi and coworkers reported that the reduction of cyclic thionocarbonates (e.g. 82) with Bu₃SnH under standard radical conditions affords cyclic acetals that can then be further transformed into 1,2-diols (equation 57)²¹⁹. This transformation represents a new approach to the protection of these diols. Zehl and Cech described the use of Bu₃SnH in the reduction of azide (83) to the corresponding amine (equation 58)³⁰⁵, while Hanessian and his associates reported the Ph₃SnH-mediated free-radical reduction of the tertiary oxalate (84) (equation 59)³⁰⁹. This transformation represents a departure from the more typical reduction of a pyridinethioneoxycarbonyl (PTOC) oxalate ester³²¹.
Shimizu and coworkers reported the use of Bu$_3$SnH for the removal of unwanted dithi-anyl groups in substituted 1,4-disilacyclohexanes (85) during their general preparation of disilacyclohexanes (equation 60)$^{311}$. Similarly, Kiyooka and his associates described the stannane-mediated removal of the thioacetal moiety in 86 during their enantioselective synthesis of a key intermediate towards the preparation of polyene macrolide filipoin III (equation 61)$^{316}$. Hiemstra and coworkers utilised Bu$_3$SnH to demercurate a key intermediate (87) during their preparation of (+)-gelsedine (equation 62)$^{315}$. In this last example, Young and coworkers describe the Ph$_3$SnH-mediated reduction of the doubly-conjugated double bond in $\beta$-ionone (88) during their preparation of theaspirane and theaspirone (equation 63)$^{319}$. This transformation had previously been reported by Wolf and Zink$^{322}$. 

![Diagram](image-url)
19. Synthetic uses of $R_3MH$ ($M = \text{Ge, Sn, Pb}$)
2. Intermolecular addition chemistry

One of the major applications of trialkyltin hydrides in synthesis has been in the formation of C–C and other bonds through the use of free-radical addition chemistry\textsuperscript{132,289,323–370}. For example, Motherwell and his associates used this free-radical methodology for the preparation of novel difluoromethylene-linked serine-\textit{O}-glycopeptide analogues (89), an example of which is depicted in equation 64\textsuperscript{338}. Junker and Fessner described the stereoselective synthesis of C-glycosylphosphonates (90) involving free-radical addition chemistry (equation 65)\textsuperscript{346}. Khan and Prabhudas reported a simple Bu\textsubscript{3}SnH-mediated preparation of bridgehead functionalised norbornene derivatives (equation 66)\textsuperscript{368}, while Naito and coworkers described a novel solid-phase synthesis use of Bu\textsubscript{3}SnH-mediated free-radical addition chemistry in the preparation of some \textit{\alpha}-amino acid derivatives (91) (equation 67)\textsuperscript{364}. Sibi, Ji and coworkers reported significant enantioselectivity during chiral Lewis acid catalysed conjugate radical addition reactions, an example of which is illustrated in equation 68\textsuperscript{331}. Indeed, other workers have also benefited through the stereochemical control provided by Lewis acids\textsuperscript{371}. For example, Tadano and his associates reported very high stereoselectivities in Lewis acid mediated conjugate radical additions in their preparation of glucopyranoside derivatives (equation 69)\textsuperscript{369}. It is interesting to note that in this example, the origin of the stereocontrol rests with the substrates, while in the former example the chiral Lewis acid played the controlling role in the chemistry.

\[\text{(69)}\]
Free-radical cyclization chemistry is now an integral part of the chemical armory available to the synthetic chemist. Indeed, during the period covered by this chapter, stannane-mediated cyclizations form by far the largest subset of chemical reactions. Mostly, this chemistry has been employed to form C–C bonds through the use of intramolecular homolytic addition methodology, although some examples involving the formation of bonds to heteroatoms via homolytic substitution chemistry are also provided. As was the case with other applications of stannanes, this section will focus on some selected examples of the chemistry in question in order to highlight the diversity available to the synthesis practitioner.

The most utilised reactions in this class involve the ‘classical’ 5- and 6-exo-trig cyclization and is typified by conversion of selenide (92) into the skeleton (93) of Garsubellin A as reported by Nicolaou and coworkers (equation 70). The radical required during the cyclization protocol can be generated in a tandem sequence as demonstrated by Marco-Contelles and Rodríguez, who reported the preparation of polyfunctionalised cyclopentanes (94) through the use of Bu$_3$SnH-mediated ring closure (equation 71). In this example, intermolecular addition of the tributylstannyl radical to the alkyne moiety in 95 is followed by rapid 5-exo intramolecular attack at the hydrazone functionality to afford the desired compound.
SCHEME 10
Bose and colleagues described the construction of tetracyclic isoquinolines and quinazolines via aryl radical cyclization (equation 72)\textsuperscript{510}. Sometimes, the radical formed as a result of 5-\textit{exo} cyclization can undergo further rearrangement as was discovered by Engman and coworkers, who report the preparation of antioxidant 2,3-dihydrobenzothiophenes (96, 97) by radical ring closure (Scheme 10)\textsuperscript{516}.

Alonso and his colleagues employed 5-\textit{exo} cyclization as part of their strategy for the synthesis of intermediates en route to (−)-tetrodotoxin\textsuperscript{660}. In this example, the radical generated after reaction of the precursor (98) with \textit{in situ} generated Bu\textsubscript{3}SnH undergoes 5-\textit{exo} ring closure onto the oxime functionality to afford the tricyclic adduct (99) (equation 73). Sometimes, intramolecular hydrogen transfer prior to cyclization can form an integral part of the overall synthetic strategy, as reported recently by Jones and coworkers during their preparation of spirooxindoles (100) (Scheme 11)\textsuperscript{663}. Malacria and coworkers employed cyclization followed by 1,4-hydrogen transfer and intermolecular addition in their recent strategy for the preparation of optically pure 1,2,3-triols (equation 74)\textsuperscript{370}. Crich and his associates investigated hydrogen transfer/cyclization methodology in their cyclization of conformationally constrained 1,3-dioxolanyl radicals (equation 75)\textsuperscript{543}.
SCHEME 11
Cyclizations onto triple bonds have also been employed commonly in the constructions of cyclic organic molecules. For example, Rainier and Kennedy utilised a tandem Bu$_3$SnH addition/cyclization strategy in their construction of some substituted indoles (101), an example of which is depicted in equation 76$^{659}$. 
Under appropriate circumstances, free-radical methods can also be used to prepare macrocyclic systems. For example, Maillard and coworkers prepared the 12-membered macrocyclic ether (102) by Bu$_3$SnH-mediated intramolecular homolytic addition to a remote, but activated ($\alpha$, $\beta$ unsaturated) olefin as depicted in equation 77$^{460}$. Tozer and coworkers employed 7-, 8- and 9-endo cyclization in their preparations of conformationally constrained amino acids (103), an example of which is provided in equation 78$^{448}$. 
Marco-Contelles and de Opazo utilised 8-endo-trig and 7-exo-dig cyclizations, mediated by Bu₃SnH, in their construction of chiral, polyfunctionalised medium-sized carbocycles. For example, treatment of iodide (104) with Bu₃SnH under standard radical conditions afforded 7-membered carbocycles (105) in moderate yield (equation 79). Prado and coworkers reported the synthesis of benzolactams by 11-endo aryl radical cyclization, an example of which is highlighted in equation 80.

While intramolecular addition chemistry has provided numerous opportunities for the preparation of bonds to carbon, there are significantly fewer examples of radical reactions that form bonds to heteroatoms. Homolytic substitution chemistry is an efficient and effective method for the formation of bonds to higher heteroatoms. Often, this chemistry is performed without the requirement for chain carriers such as Bu₃SnH. However, there are numerous examples of stannane-mediated homolytic substitution chemistry. For example, Crich and Yao use Bu₃SnH-mediated intramolecular homolytic substitution chemistry to generate acyl radicals and in doing so produce dihydrobenzothiophene as a by-product (equation 81), while work in our laboratories has demonstrated that selenocephalosporin analogues (e.g. 106) are readily available through the application of this chemistry (equation 82).

4. Tandem/cascade cyclization sequences

One of the most significant advantages of free-radical cyclization chemistry is its ability to be included in tandem or cascade sequences in which the adduct radical of a cyclization step becomes involved in subsequent cyclization chemistry. Under the right conditions, the cascade will propagate until no further intramolecular addition is possible, at which time hydrogen abstraction from a chain carrying species such as Bu₃SnH affords the final product. There are many practitioners of this art. For example, Malacria and his associates investigated the total synthesis of epi-illudol (107) via a Bu₃SnH-mediated transannular tandem sequence as depicted in Scheme 12. Lee and coworkers described a 5-exo, 7-endo sequence for the construction of the Guaianolide skeleton (108) (equation 83), while Double and Pattenden reported a series of radical cascades involving enamide bonds that lead to azasteroids (e.g. 109) (equation 84). This work follows on from earlier studies in which the same group described the preparation of steroidal structures (e.g. 110) through the use of a Bu₃SnH-mediated cascade (equation 85).
Takasu and coworkers reported the construction of the dodecahydrophenanthrene system (111) through the use of a Bu$_3$SnH-mediated 6-endo, 6-endo, 6-exo cascade process (equation 86)$^{707}$, while Sha and coworkers described the total synthesis of (+)-paniculatine (112) by a tandem sequence involving $\alpha$-carbonyl radicals (equation 87)$^{710}$.

5. Free-radical hydrostannylation reactions

Intermolecular free-radical additions of stannyl radicals to multiple bonds have emerged as important methods for the preparation of tetraorganostannanes which can be reacted further to afford new C–C bonds through transition metal mediated coupling processes (e.g. Stille coupling). There are numerous examples of this chemistry \(^{715–737}\), and this treatise will focus on a few selected examples.

Lhermitte and Carboni reported the hydrostannylation of alkynylboranes as an efficient process for the preparation of alkenyl diamino- and dialkoxyboranes (equation 88)\(^ {715}\). Regitz and his associates described the free-radical hydrostannylation of Becker-type phosphaalkenes (113) (equation 89)\(^ {719}\). The regiochemical control available during this transformation is noteworthy. Mouriño and coworkers reported the hydrostannylation of terminal acetylene (114) as part of their strategy for the synthesis of 1α,25-dihydroxyvitamin D\(_2\) (equation 90)\(^ {720}\), while Ahmed and Forsyth utilised free-radical hydrostannylation during their preparation of the C31–C46 domain of the phorboxazole natural products (equation 91)\(^ {723}\). Pearson and Lovering described the use of hydrostannylation followed by Stille coupling protocol in their preparation of key
intermediate (115) during work towards the total synthesis of (±)-crinine, (±)-6-epicrinine, (−)-amabiline and (−)-augustamine (equation 92)\(^{27}\).

\end{align*}
\]

\[(90)\]

\[(91)\]
Dussault and coworkers described the preparation of allylstannanes (116, 117) as part of their synthetic studies (equation 93). It is interesting to note the preferred geometries of the products which appear to be dependent on the nature of the stannane employed. In this last example, Yu and Oberdorfer reported the use of free-radical hydrostannylation in their preparation of (tributylstannyl)vinyl-substituted 2-deoxyuridine derivatives (e.g. 118) for use in halogenation and radiohalogenation reactions (equation 94).
6. Miscellaneous radical reactions

There are numerous reports of stannane-mediated free-radical chemistry that does not fit neatly into the categories discussed above. Some of these publications describe unusual outcomes and chemistry that is specific to a small subset of substrates, while others report radical rearrangements and fragmentations that take place after the initial, tin-mediated, radical-forming event. We have chosen a small set of examples that illustrate these concepts.

Banwell and Cameron utilised a Bu₃SnH-mediated ring-expansion process as part of their preparation of the carbon skeleton associated with manicol (equation 95). Kim and coworkers investigated 1,6-stannylation translocations between enoxy oxygen and alkoxy oxygen as part of their mechanistic investigations surrounding homolytic substitution processes (equation 96). This transformation involves addition of the stannyl radical to the double bond in 119, followed by 1,6-homolytic translocation and subsequent destannylation. Crimmins and his associates described the stannane-mediated rearrangement of cyclobutylcarbonyl radicals generated during their total synthesis of (±)-lubiminol (equation 97). Renaud and coworkers described the preparation...
of ortho-arylbenzaldehyde derivatives (121) by stannane-mediated free-radical ipso-substitution chemistry (equation 98).

(119)

\[ \text{OH} \quad \text{H} \quad \text{H} \quad \text{H} \quad \text{OH} \]

(120)
Chmielewski and colleagues reported a $\text{Bu}_3\text{SnH}$-mediated radical-induced isoxazolinedine–isoxazolidin-5-one transformation (equation 99)\textsuperscript{778}, while Sulsky and coworkers described conformational switching in the synthesis of a spiro[2H-indol]-3(1H)-ones (e.g. 122) by radical cyclization, an example of which is depicted in equation 100\textsuperscript{787}. In this final example, Takekawa and Shishido described the selective cleavage of substituted cyclopropanes via stannane-induced radical fragmentation, an example of which is illustrated in equation 101\textsuperscript{791}. \[ \text{equation 98} \]

\[ \text{equation 101} \]

$X = \text{H, CN, CF}_3, \text{OMe}$
C. Other Tin Hydrides

While the large bulk of free-radical chemistry has been carried out using reagents such as tributyl, trimethyl and triphenyltin hydride, there are several examples of the use of designer stannanes that satisfy desired niche criteria\(^\text{26–30,32–35,39–43,47–50,802–807}\). Their syntheses are described above. Some stannanes have been modified to improve their physical (solubility/separation/reactivity) properties\(^\text{27–30,47–50,804}\), while others have been tailor-made to aid in chirality transfer and to effect enantioselective outcomes during free-radical chemistry\(^\text{26,32–35,39–43}\).

For example, the fluorous stannanes (10) reported by Curran and coworkers (equation 10) are effective substitutes for Bu\(_3\)SnH in a wide cross-section of free-radical transformations\(^\text{27–30}\), as are the polymer-bound systems (37) described by Deleuze\(^\text{48,49}\).
Yoshida and coworkers described the control of free-radical reactivity during reduction by dynamic coordination; pyridylethyl-substituted tin hydrides (123, 124) appear to selectively reduce alkyl iodides and bromides in preference to chlorides, as illustrated in equations 102 and 103. Dumartin and his associates reported the immobilization of substrates required for the synthesis of 17α-(iodovinyl)estradiol through hydrostannylation with a polymer-supported tin hydride (equation 104). Baba and coworkers described the use of Bu₂SnIH in the synthesis of nitrogen heterocycles (e.g. 125) (equation 105).
Podestá and coworkers investigated 1,2-stereoinduction in the asymmetric hydrostannylation of substituted ethylenes with (−)-menthyldimethyltin hydride (equation 106)\(^802\). It is interesting to note that for the transformations investigated, high diastereoselectivity was observed. Nanni and Curran described the enantioselective reduction of bromide (126) with (S)-4,5-dihydro-4-methyl-3H-dinaphtho[2,1-c:1′,2′-e]stannepin (11) and reported enantioselectivities of up to 41% (equation 107)\(^32\). Metzger and colleagues demonstrated that the related stannane (13) provided enantioselectivities of up to 52% during the reduction of bromoester (127) (equation 108)\(^33\). In addition, the asymmetric tin hydrides (14) were demonstrated to provide enantioselectivities of up to approximately 25% at \(-30^\circ\text{C}\) in their reduction of analogous substrates (128) (equation 109)\(^806\).

Finally, Dakternieks, Schiesser and coworkers reported the highest enantioselectivity for a free-radical reduction reaction (96% ee) by combining the controlling effects of both chiral, non-racemic stannane (15, 17, 18–22, 27) and sterically demanding Lewis acid\(^807\). In the example provided in equation 110, the authors demonstrate that the chirality of the Lewis acid was largely irrelevant because both enantiomeric forms of Jacobsen’s catalyst provide essentially the same outcome. Several other examples are provided\(^807\).

IV. TRIALKYLTIN HYDRIDES IN NON-RADICAL CHEMISTRY

As already demonstrated, stannane chemistry often involves the intermediacy of free radicals. There are some notable examples, however, of non-radical transformations involving trialkyltin hydrides. This (much smaller) subset of reactions is dominated by transition metal catalysed hydrostannylation chemistry, chemistry that rivals the free-radical examples provided above. In addition, there are a few examples of ionic reduction chemistry involving these reagents.

Ferri and Alami investigated the use of palladium-mediated hydrostannylation of dienynes (e.g. 129) in their preparation of precursors related to the neocarzinostatin chromophore (equation 111). While most transformations proceeded with little regioselectivity, some examples, most notably with TMS substitution, provided good selectivity. Xiang, Mahadevan and Fuchs reported the stereo- and regioselective syntheses of α- and β-vinyl and dienyl triflones via Stille coupling; hydrostannylation provided the Stille precursors (e.g. 130) (equation 112). Crisp and Gebauer investigated the hydrostannylation of propargylglycine derivatives facilitated by a number of transition metal catalysts (equation 113), while Lautens and coworkers described the regioselective hydrostannylation of allenes catalysed by Pd(OH)₂/C (equation 114).

\[

\text{SnBu₃} & \quad \text{Bu₃SnH} & \quad \text{Bu₃SnH} \\
\end{align*}
\]
Uenishi and coworkers utilised palladium-catalysed hydrostannylation of dibromoalkenes (e.g. 131) as a method for the preparation of precursors en route to (Z)-alkenyl bromides (equation 115)\(^{831}\). These transformations effectively amount to hydrogenolysis and are believed to proceed by the mechanism depicted in Scheme 13\(^{831}\).

Kazmaier and his associates introduced Mo(CO)\(_3\)(CNBu-\(t\))\(_3\)(MoB\(_3\)I\(_3\)) as a new and efficient catalyst for regioselective hydrostannylation chemistry (equation 116)\(^{844}\), while Smith and Lodise described the assembly of a subtarget of 13-deoxytedanolide using hydrostannylation as an important step (equation 117)\(^{845}\). Rizzacasa and his colleagues utilised palladium-catalysed hydrostannylation in the preparation of an important synthon.
Bertrand and his associates reported the hydrostannylation of phosphorus vinyl ylides (133) by the action of tributyltin hydride in the absence of either a catalyst or free-radical initiator (equation 119). Yamamoto and coworkers described the Lewis acid catalysed hydrostannylation of C—C multiple bonds by Bu₃SnH produced in situ by the reaction...
of Bu₃SnCl with Et₃SiH (equation 120).\(^{862}\)

\]

### V. TRIALKYLGERMANIUM AND LEAD HYDRIDES IN SYNTHESIS

As discussed earlier in this chapter, trialkylgermanium hydrides are sometimes used in place of the more favoured tin counterparts, especially in radical chemistry when the rate constant for the primary bond-forming process lies outside the range acceptable for stannane chemistry. The reader will recognize without too much difficulty the scarcity of reports utilising germanium reagents when compared to those employing the analogous tin reagents. This is largely due to the relative expense of germanium compared to tin, but the lack of user-friendly NMR techniques for germanium compounds is also a contributing factor. Nevertheless, in the period covered by this review there have been some notable uses of germanes in preparative chemistry.\(^{26,309,413,863–865}\) To the best of our knowledge, there have been no applications of lead hydrides in synthesis during the same period.

The preparations of novel germanium hydrides have been discussed above. In some of these papers, the synthetic utility of these new reagents is also explored. For example, Oshima and coworkers described the use of tri-2-furanylgermanium hydride (2) as an alternative reagent for the generation of alkyl radicals from the corresponding halide and demonstrated standard reduction and cyclization protocols.\(^{19,863}\) While Mochida and coworkers examined the reactivity of novel polymer-supported germanes as free-radical reducing agents.\(^{25}\)

In other reports, Kim and coworkers reported the 1,5-translocation of the triphenylgermyl group between enoxy and alkoxy oxygen, an example of which is illustrated in equation 121.\(^{749}\) In addition to the stannane-based rearrangements described above (equation 96), Ryu and his associates demonstrated the difference between the products obtained in Bu₃GeH-mediated carbonylation/cyclization chemistry over the more traditional tin reagent (equation 122) and attribute the outcome to the poorer hydrogen-donating ability of the germane.\(^{413}\) Nishiyama and colleagues described the Et₃GeD-mediated selective deoxygenation and deuteriation of proline derivatives (equation 123).\(^{307}\)
19. Synthetic uses of $R_3MH$ ($M = Ge, Sn, Pb$)

In these final examples, Otero and coworkers described the reaction of a niobocene hydride (134) with triphenylgermanium hydride to afford niobocene germyl complexes (135) (equation 124)\(^864\), Spino and Barriault reported the radical cyclization of polyenes (136) mediated either by trialkyltin or trialkylgermanium hydride, an example of which is depicted in equation 125\(^705\), while Wittman and coworkers used Bu$_3$GeH during their construction of 7-deoxy-6-hydroxypaclitaxel (equation 126)\(^865\); the use of Bu$_3$SnH was not successful in this case as the stannane appeared to also remove the 10-acetate in the precursor (137).
Lastly, Gualtieri reported the use of binaphthyl-substituted germanes (8, 9) in enantioselective radical chemistry\(^\text{26}\). For example, an enantioselectivity of 59\% was reported for the reaction of 126 with 8 at \(-60^\circ\) (equation 127). To the best of our knowledge, this represents the first account of the use of a chiral germanium hydride in free-radical reduction chemistry.

VI. ACKNOWLEDGEMENT

We gratefully acknowledge the assistance of Miss Olympia Stamkos in the final stage checking of the references to this chapter.

I. INTRODUCTION

Advances in the chemistry of haloforms and its analogue HMHal₃ (M = C, Si, Sn) served the development of organic and organometallic chemistry in just degree. Thus, preparative carbene chemistry started from the chemistry of dichlorocarbenes¹ and investigation of base hydrolysis of chloroform led not only to simple and effective methods of dichlorocyclopropane synthesis², but also to the beginning of a new discipline—phase transfer catalysis³. The study of thermolysis of haloforms led to the creation of the original and highly effective method of synthesis of halodiaromatic compounds and, especially, of deficient fluoroaromatics⁴.

Silicachloroform HSiCl₃, germanachloroform HGeCl₃ and the acidic form of stannachloroform H⁺SnCl₃⁻ were and remain basic reagents of group 14 for hydrometallation of unsaturated compounds. The lead analog of chloroform is unknown; the calculated value of its exothermic decomposition: HPbCl₃ → PbCl₂ + HCl is 29 kcal mol⁻¹⁵.

Trichlorogermane is a demarcative compound in this series because it exists in both covalent (HGeCl₃) and ionic acidic (H⁺GeCl₃⁻) forms⁶. The easy accessibility and high reactivity of HGeCl₃ together with a great variety of its chemical properties determine its special place among the key starting materials for the synthesis of organogermanium compounds up to the present day. Compounds of potential pharmacological activity, such as germatranes and germasesquioxides⁷,⁸, germanium containing nucleosides⁹, antibiotics and steroids¹⁰ can be easily obtained via reactions of trichlorogermane.

The great diversity of the chemical properties of trichlorogermane is especially astonishing and even discouraging. Thus, hydrogermylation reactions of various multiple bonds by trichlorogermane, which can proceed via either ionic or radical mechanisms, are widely known. Likewise, hydrogermylation of cyclopropane and aromatic compounds are also known. In the latter case, the superacidic properties of trichlorogermane develop most spectacularly.

Numerous reactions of trichlorogermane with organic halides, resulting in compounds of general formula RGeCl₃, are of preparative importance. Here again, two basic mechanisms are possible: nucleophilic Cl⁻ substitution by the GeCl₃⁻ and insertion of dichlorogermylene, previously generated from trichlorogermane, in C–Hal bonds.

Trichlorogermane, and especially its etherates, behave as a source of dichlorogermylene in many reactions. Investigations in this direction and, primarily, synthesis and studies of molecular complexes of GeCl₂ with n-donor ligands largely determined the development of the chemistry of germelenes and other carbenoids of the group 14 elements.

Trichlorogermane reactions involving participation of dichlorogermylene are not oxidation–reduction reactions in the usual sense of this term, though they are described by Ge²⁺/Ge⁴⁺ transfers. At the same time, the reductive properties of trichlorogermane can be illustrated by the reduction of nitrobenzenes to anilines.

Finally, the reaction of double germylation, such as formation of Cl₃GeCH₂CH₂GeCl₃ from ethylene and the etherate of trichlorogermane, is of great importance.
Experimental data of reactions of trichlorogermane are reviewed elsewhere. The main aim of this chapter is to gather investigations of the mechanistic aspects of reactions of trichlorogermane and to apply these data for providing a rational explanation of the experimental facts.

II. SYNTHESIS, STRUCTURE AND PHYSICAL PROPERTIES OF TRICHLOROGERMANE

Germanium is disposed in the center of group 14 of the periodic table of the elements. Increased stability of divalent species, which is more pronounced for tin and lead, begins from this element. The main characteristics of these atoms, such as atomic radius, energy of ionization, electron affinity, electronegativity and other features, are presented in parallel in a review.

Formally, HGeCl₃ belongs to inorganic chemistry and should be named trichlorogermandium hydride. We will follow the organic chemistry nomenclature and use the name trichlorogermane.

The simple ‘elementary synthesis’ of trichlorogermane from metallic Ge involves passing of dry HCl gas over Ge powder in a quartz tube at an elevated temperature in the presence of Cu powder. Consequently GeCl₄ is present in crude trichlorogermane obtained by such ‘elementary synthesis’ up to 20–40%. Pure trichlorogermane can be obtained in 40% yield by interaction of dry GeS and HCl followed by distillation. Extrusion of highly pure trichlorogermane by AlCl₃ from its etherates, which in turn can be obtained in an appropriate quality from trichlorogermane formed by the ‘elementary synthesis’, is probably the most convenient method.

Precautions are necessary when operating with trichlorogermane which is dry and free of GeCl₄, since impurities are formed as a result of any oxidative contact with air according to \( \text{HGeCl}_3 + \text{O}_2 \rightarrow \text{GeCl}_2 + \text{GeCl}_4 + \text{H}_2\text{O} \). Moreover, trichlorogermane can partially lose HCl even at \(-30\,^\circ\text{C}\) and therefore can be enriched by GeCl₂ and Ge subchlorides. That is the reason why experimental measurements of the physical properties of purified trichlorogermane are only few. There are no data on X-ray, electron diffraction spectroscopy in the vapor phase, mass-spectrometry and dipole moment determinations.

Trichlorogermane is colorless, mobile and a volatile liquid, \( d_0 = 1.93\,\text{g cm}^{-3} \), \( \text{mp} = -71\,\text{^\circ C} \), \( \text{bp} = 75.2\,\text{^\circ C} \). AM1 calculations give rise to the following geometric parameters of HGeCl₃ of \( C_{3v} \) symmetry: bond lengths of Ge–H = 1.559 Å, Ge–Cl = 2.131 Å, and bond angle of ClGeH = 111.6°. As follows from Raman spectroscopy data, dry trichlorogermane has a tetrahedral structure with calculated bond lengths of Ge–H = 1.55 Å, Ge–Cl = 2.11 Å, and Cl–Ge–Cl angle = 108.17°. The values of the valent and deformation frequencies of Ge–H are 699 and 2159 cm⁻¹ and the force constant is 2.7 × 10⁵ dyn cm⁻¹. In contrast, the spectrum of trichlorogermane in hydrochloric acid solution is completely different from the tetrahedral spectrum and belongs to the trigonal-pyramidal ion GeCl₃⁻. Bond lengths of Ge–Cl are 2.29–2.30 Å and Cl–Ge–Cl angles 93.4–98.3° were obtained for this trigonal-pyramidal species by X-ray analysis of [BnEt₃N]⁺GeCl₃⁻.

The extraordinarily big shift of the nuclear quadrupole resonance frequency in the etherate of trichlorogermane in comparison with trichlorogermane itself (9 MHz; from 23 to 14 MHz) can also be explained by a change in the coordination of the central atom to the trigonal-pyramidal form.

The principal thermodynamic functions calculated from the spectral data are collected elsewhere. The Ge–H chemical shift in the \(^1\text{H} \text{NMR} \) spectrum is at 7.6 ppm and has a half-width of \( ca. \) 7.2 Hz. This can be taken as evidence for exchange in the presence
of protic impurities. Attempts to obtain a $^{73}\text{Ge}$ NMR spectrum of HGeCl$_3$ and find out Ge–H satellites by using natural isotopic abundance of Ge had failed.$^{22}$

Among the different salts of the type MGeCl$_3$, the Rb and Cs salts, but not the Li and Na salts, are stable and well studied. This is accounted for in terms of ‘sharp’ and ‘soft’ acids and bases. In contrast to the small and ‘sharp’ Li$^+$ and Na$^+$ ions, the big and ‘soft’ Rb$^+$ and Cs$^+$ ions fit well the bulky and soft GeCl$_3^-$ anion.

### III. ACIDIC AND SUPERACIDIC PROPERTIES OF TRICHLOROGERMANE

#### A. Chemical Examples and Determinations

The acidic properties of covalent trichlorogermane cannot be characterized by the extent of dissociation. Unlike the etherate (Et$_2$O)$_2$HGeCl$_3$, free HGeCl$_3$ does not react with magnesium with the evolution of hydrogen. This simple observation attests to the fact that trichlorogermane behaves as an acid being ionized in basic solution, for instance, in ether (equation 1).

$$\text{HGe}^{+}\text{Cl}_3 \rightleftharpoons \text{H}^+\text{Ge}^{2+}\text{Cl}_3^- \rightleftharpoons \text{HCl} + \text{Ge}^{2+}\text{Cl}_2$$

If H$^+\text{GeCl}_3^-$ is considered as the conjugate Brønsted–Lewis acid of HCl and GeCl$_2$, it follows that the dichloride GeCl$_2$ must be characterized as a Lewis acid. According to the electron deficiency criterion, the GeCl$_2$ molecule, which possesses a vacant p-orbital, is, like AlCl$_3$, BF$_3$, ZnCl$_2$ etc., a Lewis acid and forms complexes of the type B•GeCl$_2$ with Lewis bases. The complexes of this type were already prepared in 1966. Among these molecular complexes, C$_4$H$_8$O$_2$•GeCl$_2^{23,24}$, Ph$_3$P•GeCl$_2^{25}$ and C$_5$H$_5$N•GeCl$_2^{26}$ have been studied in detail. As a Lewis acid, GeCl$_2$ may exhibit catalytic activity in Friedel–Crafts reactions. Although this activity has not been particularly studied, we should note the ability of polymeric germanium dichloride (GeCl$_2$)$_x$ to catalyze self-alkylation (condensation) reactions of benzyl chloride.$^{27}$ Hence, the acid H$^+\text{GeCl}_3^-$ fits into the series of superacids H$^+\text{AlCl}_4^-$, H$^+\text{BF}_4^-$ etc. which are also referred to as Friedel–Crafts acids.$^{28}$

The exact determination of the acidic properties of trichlorogermane is experimentally difficult. First, it should be remembered that solvate-free trichlorogermane is a covalent compound. Only the presence of species such as an ether, amine or phosphine change the nature of trichlorogermane so that it easily ionizes. Hence, the acidic properties of H$^+\text{[GeIICl}_3]$ in the solvated form can only be estimated indirectly.

Compounds which have absolute values of the Hammett acidity function ($H_o$) greater than that of 100% H$_2$SO$_4$ ($H_o = -11.9$) are classified as superacids.$^{29}$ It has been found that, like other superacids, trichlorogermane bleaches colored nitroaniline indicators, including 2,4,6-trinitroaniline, which are used for the determination of the Hammett acidity function $H_o$. However, the quantitative determination of $H_o$ by means of these reagents is not possible since trichlorogermane, being a strong reducing agent, is capable of reducing the NO$_2$ groups in the aromatic nitro-substituted indicators to amino groups.$^{30}$

Due to this difficulty, trichlorogermane has been classified as a superacid by means of the IR-spectroscopic method used for estimating the proton donating capabilities of acids.$^{31}$ This method is based on the fact that, when acids AH and a base B interact strongly, the protonated form BH$^+$ is considered as an acid which forms a hydrogen bond in the ion pairs BH$^+$•••A$^-$. When this occurs, the shift in the B–H vibrational frequencies (more correctly, the gravity centers of the continuous absorption) is used for the comparative estimation of the strength of bases A$^-$, i.e. for the estimation of the effective p$K_a$ values of the corresponding acids AH. By using this method, it was shown that the acidity of HGeCl$_3$ is close to the acidity of HClO$_4$, having a $H_o$ value of \(ca \ -13.0^{28}\).
The superacidic properties of trichlorogermane are clearly manifested in the properties of its etherates (vide infra) and the ability of DGeCl₃ to participate in a deuterium–hydrogen exchange reaction with methylbenzenes³² (Section VIII.E).

The surprising reactivity of trichlorogermane, which is greater than the reactivity of the other hydrides of group IV.B elements, becomes comprehensible when viewed from the point of view of its superacidity. Several reactions of trichlorogermane, which take place at room temperature or on moderate heating in the absence of any catalyst, are shown in Figure 1. In parallel, other reactions, such as aldol condensation of carbonyl compounds or cleavage of ether C—O bonds, take place due to the acidic properties of trichlorogermane. The formation of the products can be explained by the formation and participation of intermediate carbocations, arenium ions, acyl cations and oxonium ions.

It is impossible not to note the remarkable similarity between Figure 1 and the scheme for the formation of stable carbocations presented in Olah’s ‘superacids’ review²⁸. It is only for the activation of the C—H bond in hydrocarbons that trichlorogermane turns out to be an insufficiently strong acid.

The basic difference between HGeCl₃ and other superacids lies in the properties of the GeCl₃⁻ counterion. It is known that the counterions of classical superacids are characterized by an exceptionally low nucleophilicity which is widely used for the preparation and study of stable carbocations. On the other hand, HGeCl₃ is an example of a superacid whose counterion GeCl₃⁻ tends to undergo a rapid combination with many organic cations to form stable covalent compounds having a strong enough Ge—C bond (bond energy of
57–59 kcal mol$^{-1}$). However, as will be discussed below, the GeCl$_3^-$ anion does not recombine with all cations. The existence of a stable iminium salt, a cyclohexenyl cation and a σ-complex with a GeCl$_3^-$ counterion provides a convincing example for this. Hence, trichlorogermapne is an unusual example of an acid with an anion having an intermediate nucleophilicity with accompanying protonating ability corresponding to those of superacids.

B. Etherates of Trichlorogermapne

Investigations of the etherates of trichlorogermapne also confirm that H$^+$GeCl$_3^-$ is to be classified as a Friedel–Crafts superacid. The exothermic reaction of diethyl ether with trichlorogermapne leads to the etherate (Et$_2$O)$_2$•HGeCl$_3$, which is an oily liquid of salt-like structure that does not mix with an excess of ether. Other simple ethers also form similar etherates with HGeCl$_3$. In the majority of cases these species act as sources of GeCl$_2$. The structure of the etherate [Et$_2$O → H ← OEt$_2$]$^+$GeCl$_3^-$ was first proposed on the basis of the IR and NMR spectra.

More recently, it was shown that the etherates of Friedel–Crafts superacids, including the etherate of trichlorogermapne, are systems with a short (strong) hydrogen bond which manifests itself in a characteristic manner in $^1$H and $^{13}$C NMR spectra and as a continuous absorption (continuum) in the 1000–3000 cm$^{-1}$ region in the IR spectra. A complete X-ray structural investigation has been carried out for etherate (Et$_2$O)$_2$•HZnCl$_3$ and its deuterio analogue (Et$_2$O)$_2$•DZnCl$_3$. It was shown that (Et$_2$O)$_2$•H(D)ZnCl$_3$ crystals consist of the centrosymmetric dianions Zn$_2$Cl$_6^{2-}$ and [Et$_2$O•••H(D)•••OEt$_2$]$^+$ cations. The O•••H•••O bond length of 2.39 Å has one of the shortest distances for hydrogen bonds involving oxygen atoms.

No doubt, the ether moiety of the etherate of trichlorogermapne has the same structure as a [Et$_2$O•••H•••OEt$_2$]$^+$ cation. The principal difference between Zn and Ge etherates is only in the structure of the GeCl$_3^-$ anion, which is monomeric. According to estimates, the lengths and ionicities of the bonds in the GeCl$_3^-$ anion must be close to those for the [BnEt$_3$N]$^+$GeCl$_3^-$ salt and for the C$_4$H$_8$O$_2$•GeCl$_2$ complex, since the $^{35}$Cl NQR frequencies for these two compounds are in the same frequency region of 13.4–14.4 MHz.

C. Stable Organic Salts with a GeCl$_3^-$ Anion

The ability of trichlorogermapne as an acid to form stable organic salts having the GeCl$_3^-$ anion was first observed in the study of the reaction of HGeCl$_3$ with triphenylamine. It was found that at room temperature their interaction lead to the formation of an unusual iminium salt, i.e. trichlorogermapnate 3,5-bis(trichlorogermyl)cyclohexylidendiphenyliminium in 92% yield (equation 2).
A detailed follow-up of the reaction by $^{13}$C NMR spectroscopy has shown that the initially formed species is an isomer of 1 with a *trans*-configuration of the germyl groups with respect to the plane of the cyclohexane ring which exists in the twist-conformation. Over a period of two hours at 25°C, 85% of the *trans*-isomer 1 isomerizes into the *cis*-isomer of 1 and there is no further change in the ratio of the isomers. The crystalline *cis*-isomer of 1 has been isolated in a pure form and fully characterized.

A principal result was obtained in the study of HGeCl$_3$ reaction with 1,3-diethoxybenzene. In this reaction at $-50^\circ$C in CD$_2$Cl$_2$ the 1,3-diethoxy-5-trichlorogermylcyclohexenyl cation 2, stable under these conditions during many hours, was formed (equation 3)$^{37}$.

\begin{equation}
\text{EtO} \quad + \quad \text{HGeCl}_3 \quad \xrightarrow{50^\circ \text{C}} \quad \begin{array}{c}
\text{EtO} \\
\text{Cl}_3\text{Ge} \\
\text{OEt}
\end{array} \quad \text{GeCl}_3^- \\
(2)
\end{equation}

This first carbocation of the allyl type stabilized by a GeCl$_3^-$ anion is being formed in a yield close to quantitative and it was easily characterized at $-50^\circ$C by IR, UV, $^1$H and $^{13}$C NMR spectra.

Finally, in the case of the reaction of HGeCl$_3$ with 1,3,5-trimethoxybenzene the authors hoped to detect experimentally the $\sigma$-complex. Actually, as shown in equation 4, in the course of this reaction in a CD$_2$Cl$_2$ solution a quantitative formation of the arenium ion 3 was observed$^{38}$.

\begin{equation}
\text{MeO} \quad + \quad \text{HGeCl}_3 \quad \xrightarrow{20^\circ \text{C}} \quad \begin{array}{c}
\text{MeO} \\
\text{MeO} \\
\text{OMe}
\end{array} \quad \text{GeCl}_3^- \\
(3)
\end{equation}

This ion was stable for an hour even at room temperature. It was characterized by IR, UV, $^1$H and $^{13}$C NMR spectra. It can be assumed that the GeCl$_3^-$ anion has a quite low nucleophilicity in these salts, similarly to the anions of classic superacids.

At the end of this section one point should be especially emphasized: the superacidic properties of ionic H$^+$GeCl$_3^-$ are not astonishing, but rather the existence of HGeCl$_3$ itself in a covalent form. Quantum chemical calculations show that the affinity of GeCl$_3^-$ to the proton is only slightly different from the ionization potential of the hydrogen atom$^{39}$. In other words, the ‘sharp’ proton H$^+$ and the ‘soft’ anion GeCl$_3^-$ should separate if the electrostatic interaction is compensated by the energy of solvation.
Besides, the extents of dissociation of water-free superacids are insignificant, since the acids themselves are poor solvative media. They are less basic than water and poorly solvate protons. On the other hand, the solvation by superacids of the negatively charged anions is higher than in water solution. This is why the strength of acids is manifested by their protonation ability, rather than by the extent of dissociation\(^\text{40}\). This accounts for the high protonating ability of superacids, and trichlorogermane in particular, in the absence of ionizing solvents.

**IV. ELECTROCHEMICAL INVESTIGATION OF HGeCl\(_3\) AND GeCl\(_4\)**

Electrochemistry of organogermanium compounds is still insufficiently studied. However, a systematic electrochemical study of basic germanium chlorides HGeCl\(_3\) and GeCl\(_4\) was carried out\(^\text{41,42}\). The main principles of the electrode processes and the nature of the intermediates formed were determined.

**A. Oxidation**

The polarization curves of CsGeCl\(_3\), PyHGeCl\(_3\) and HGeCl\(_3\)•2Et\(_2\)O oxidation (0.1 N Et\(_4\)NClO\(_4\) in absolute CH\(_3\)CN, Pt rotating disk electrode) gave one anodic wave \((E_{1/2} = 0.5 \text{ V})\), corresponding to anion GeCl\(_3^-\) oxidation. In the course of the experiment the height of this wave decreases and another wave \((E_{1/2} = 0.9 \text{ V})\), corresponding to Cl\(^-\) oxidation, appears. This was explained by GeCl\(_3^-\) dissociation to GeCl\(_2\) and Cl\(^-\) under favorable conditions.

Trichlorogermane itself is ionized in CH\(_3\)CN solution. Therefore, as in the above mentioned cases, the anion GeCl\(_3^-\) undergoes oxidation. The polarization curve of trichlorogermane oxidation under the same conditions gave an anodic one-electron wave with \(E_{1/2} = 0.48 \text{ V}\).

In general, the trichlorogermane oxidation is described by equation 5.

\[
\begin{align*}
\text{HGeCl}_3 & \rightleftharpoons \text{H}^+ + \text{GeCl}_3^- \rightleftharpoons \text{GeCl}_3^* \xrightarrow{\text{dimerization}} \text{Ge}_2\text{Cl}_6 \\
\text{(GeCl)}_x & \leftrightarrow \text{GeCl}_2 + \text{GeCl}_4
\end{align*}
\]

Preparative electrolysis of HGeCl\(_3\)•2Et\(_2\)O leads, as expected, to the formation of GeCl\(_4\) and Ge-subchlorides.

**B. Reduction**

The reduction of GeCl\(_4\) also proceeds easily. The polarizing curve for the reduction of GeCl\(_4\) (0.1 N Bu\(_4\)NClO\(_4\) in absolute CH\(_3\)CN, Pt rotating disk electrode) has a single two-electron cathodic wave with \(E_{1/2} = -0.35 \text{ V}\). The electron number was determined coulometrically. At the controlled potential electrolysis \(E = -0.4 - 0.5 \text{ V}\) the height of the cathodic wave decreased and, at the same time, two anodic waves with \(E_{1/2} = 0.5 \text{ V}\) and \(E_{1/2} = 0.9 \text{ V}\) appeared. Judging from the \(E_{1/2}\) value, these waves could correspond to GeCl\(_3^-\) and Cl\(^-\) oxidation. According to the Pt rotating ring-disk electrode experiment, the GeCl\(_3^-\) anion is relatively stable and exists for a while in solution before its dissociation into GeCl\(_2\) and Cl\(^-\).
In general, the GeCl$_4$ reduction is reflected by equation 6.

\[
\text{GeCl}_4 + 2e^- \rightarrow \text{Cl}^- + \text{GeCl}_3^- \rightarrow \text{Cl}^- + \text{GeCl}_2 \rightarrow (\text{GeCl})_x
\] (6)

Some organogeranium compounds were first synthesized by interaction of different RHal species and electrochemically generated anion GeCl$_3^-$ (equation 7).

\[
\text{GeCl}_3^- + \text{RHal} \rightarrow \text{RGeCl}_3 + \text{Hal}^-
\] (7)

\[
\text{R} = \text{Me, Ph, Bn, AlI, Ac}
\]

\[
\text{Hal} = \text{Cl, Br, I}
\]

The counterion of the electrochemically generated GeCl$_3^-$ is the cation of the supporting electrolyte. By changing the electrolyte, it is possible to vary the GeCl$_3^-$ lifetime and to change the route of the electrochemical processes.

Thus, the results of the electrochemical study confirm the ready Ge$^{II} - \text{Ge}^{IV}$ transformation in chemical reactions. The easy oxidation of GeCl$_3^-$ to the GeCl$_3^+$ radical should be especially noted since it explains the appearance of GeCl$_3^+$ radicals in chemical reactions free of radical initiators.

**V. REACTIONS OF TRICHLOROGERMANE WITH ORGANIC HALIDES**

Interaction of trichlorogermane, and especially its etherates and aminates, with reactive organic halides results in nucleophilic substitution on organic halides by the trichlorogermyl group (equation 8)\textsuperscript{43,44}.

\[
\text{HGeCl}_3 + \text{R} - \text{Cl} \rightarrow \text{RGeCl}_3 + \text{HCl}
\] (8)

\[
\text{R} = \text{AlI, Bn, MeOCH}_2, \text{Me}_3\text{C, Ph}_3\text{C, 1-Ad etc.}
\]

Halohydrocarbons with labile bromine atom react even more easily. On the other hand, organic halides with less labile halogen atoms require more drastic reaction conditions, and sometimes even the application of pressure. In its entirety the reaction is a useful method for synthesis of organotrichlorogermanes. There are no analogous reactions in the chemistry of chloroform and trichlorosilane and the logical explanation of the phenomena can be found in the concept of HGeCl$_3$ superacidity.

This reaction, inaptly named condensation reaction\textsuperscript{43}, proceeds either by a nucleophilic substitution mechanism or by insertion of dichlorogermylene into the C–Cl bond. The nucleophilic substitution mechanism is doubtful. In accordance with quantum-chemical calculations, the negative charge in the anion GeCl$_3^-$ is distributed on chlorine atoms and a movement of anion to the cation from the ‘rear’ results in Cl$^-$ loss and GeCl$_2$ formation\textsuperscript{39}.

As shown by calculations, the carbenoid mechanism of dichlorogermylene insertion in ordinary C–Cl bond begins by electrophilic attack of the vacant p-orbital of the Ge atom on the electrons of the bond\textsuperscript{45,46}. The vacant p-orbital does not interact with the unpaired electrons of the chlorine atoms. When the distance between the reactants decreases and becomes close to the value of the C–Cl bond length, inactivated transfer of Cl to the germylene center occurs with formation of a radical pair, followed by its recombination. The closer the components of the radical pair, the smaller the probability of radicals movement away from one another. The theoretical interest concerning the details of the germylene insertion mechanism is continuing. Thus, a quantum-chemical examination of
the hypothetical insertion reaction of GeCl₂ into the C–H bond of methane was carried out recently⁴⁷,⁴⁸.

The insertion reaction can be easily modeled by using the dioxane complex of dichlorogermylene²⁴,⁴⁹. Kinetic investigation of the reaction with benzyl chloride was carried out⁵⁰. The experimental data were in line with kinetic equation 9, which involves participation of a free dichlorogermylene in the insertion step (in dioxane solution, where the equilibrium is shifted to the left, the insertion reaction does not occur).

$$ \text{C}_4\text{H}_8\text{O}_2 \cdot \text{GeCl}_2 \xrightleftharpoons[k_1]{k_{-1}} \text{GeCl}_2 + \text{C}_4\text{H}_8\text{O}_2 $$

$$ \text{BnCl} + \text{GeCl}_2 \xrightarrow{k_2} \text{BnGeCl}_3 \tag{9} $$

The experimental value of the energy of activation for the GeCl₂ insertion into the C–Cl bond was first found to be $E_a = 14.1$ kcal mol⁻¹. This value is substantially higher than the energy of activation for carbene insertion into ordinary bonds, estimated to be 5–7 kcal mol⁻¹⁵¹. This fact demonstrates the difference in reactivity and selectivity of the divalent species. A large and negative value of the entropy of activation ($\Delta S^\# = -35.9 \pm 4.4 \text{ eu}$) shows that the transition state of the dichlorogermylene insertion step is highly ordered.

Some other attempts to distinguish the two above mentioned mechanisms meet difficulties resulting from halogen lability. Thus, using in the reaction the optically active isomer of PhCH(Me)Cl led to complete racemization in both the starting material and the products²². Radiochemical investigation of the reaction with Bn³⁶Cl failed because full halogen exchange between the precursors took place²⁷.

A concerted insertion mechanism with highly ordered transition state, close to three-centered, was corroborated by examination of the kinetic isotope effect, which was measured by competitive GeCl₂ insertion reactions into the C–Cl bonds of labeled ¹⁴CCl₄ and ¹²CCl₄. The value obtained, $k_{14}/k_{12} = 1.01 \pm 0.01$, is very close to that calculated from the stretching frequencies and the ratio of the masses and moments of inertia of the isotopic molecules for a synchronous reaction (0.993) and differs significantly from the calculated value for a dissociative mechanism (0.900)⁵².

Finally, radiochemical investigation of the interaction of HGeCl₃ and C³⁶Cl₄ excluded an ionic mechanism for Cl₃CGeCl₃ formation in the reaction shown in equation 10.

$$ \text{CCl}_4 + \text{HGeCl}_3 \xrightarrow{k} \text{HCCl}_3 + \text{GeCl}_4 (83\%) $$

$$ \text{Cl}_3\text{CGeCl}_3 + \text{HCl (17\%)} $$

The value for the relative radioactivity of chlorine in the Cl₃CGeCl₃ attests to a carbene-like mechanism in its formation with a probability of 99%⁵³.

### VI. REACTIONS OF TRICHLOROGERMANE WITH UNSATURATED COMPOUNDS

**A. Ionic and Radical Mechanisms in Reactions of Hydrogermylation**

Trichlorogermane reactions with olefins and acetylenes, including functionally substituted compounds, are one of the basic methods of obtaining organogermanium derivatives. Trichlorogermane adds easily in the absence of any catalyst to olefinic and acetylenic
bonds, even unactivated ones. Numerous examples of such reactions are collected, for example, in a monograph\(^7\) and a review\(^11\). Having in mind the acidic properties of trichlorogermane, one can assume that hydrogermylation reactions will proceed by an ionic mechanism with formation of products according to ‘Markovnikov’ regioselectivity. However, numerous literature data testify to an opposite tendency. With very rare exceptions, addition to olefins and acetylenes proceeds against ‘Markovnikov’ orientation. Moreover, the original papers and reviews assert the formation of only ‘anti-Markovnikov’ adducts. Such a type of addition was called the ‘Farmer rule’\(^54\). In spite of the presence of a large amount of experimental data, the mechanism of the reaction was practically unstudied. Thus, addition of trichlorogermane to the allyl but not the vinyl group in dimethylallylvinyilsilane was logically ascribed to an ionic mechanism\(^55\). A study of the regioselectivity of the hydrogermylation of isopropenylacetylene shows that the olefinic bond is more active than the acetylenic bond\(^56\). The authors prefer a radical mechanism for the reaction, but they did not study it.

A detailed study of the reactions of trichlorogermane with unsaturated compounds was performed\(^57\text{–}59\). It became clear that among selected olefins only 1-heptene forms the anti-Markovnikov adduct in the reaction with trichlorogermane. In contrast to the generally accepted opinion, in the reactions with 1-methylcyclohexene (equation 11), styrene (equation 12), 2,3-dimethyl-1-butene (equation 13) and isobutene (equation 14) both regioisomers 4 and 5, 6 and 7, 8 and 9, and 10 and 11 appear in commensurable amounts (together with oligomeric products; see later, equation 16).

\[
\begin{array}{cccc}
\text{PhCH} &=& \text{CH}_2 + \text{HGeCl}_3 & \xrightarrow{-5^\circ\text{C}} & \text{PhCH}_2\text{CH}_2\text{GeCl}_3 + \text{PhCH}(\text{GeCl}_3)\text{Me} \\
& (6) & 28.5\% & (7) & 12.5\% \\
\text{Me}_2\text{CHC(Me)} &=& \text{CH}_2 + \text{HGeCl}_3 & \xrightarrow{-5^\circ\text{C}} & \text{Me}_2\text{CHCH(Me)CH}_2\text{GeCl}_3 \\
& (8) & 49\% & + & \text{Me}_2\text{CHC(GeCl}_3\text{)Me}_2 \\
& (9) & 10\% \\
\text{Me}_2\text{C} &=& \text{CH}_2 + \text{HGeCl}_3 & \xrightarrow{-10^\circ\text{C}} & \text{Me}_2\text{CHCH}_2\text{GeCl}_3 + \text{Me}_3\text{CGeCl}_3 \\
& (10) & 50\% & (11) & 8\%
\end{array}
\]

Reaction of trichlorogermane with excess of styrene at \(-5^\circ\text{C}\) leads to the formation of both isomers with a 2.3 : 1 predominance of the ‘anti-Markovnikov’ product. This ratio can be modified by varying the reaction conditions. Thus, if the reaction is carried out in concentrated HCl, the yield of 7 rises up to give an opposite regiochemistry with a ratio 6 : 7 = 1 : 9. The role of concentrated HCl consists in the ionization of trichlorogermane and shift of equilibrium \(\text{GeCl}_3^- \rightleftharpoons \text{GeCl}_2 + \text{Cl}^-\) to the left in the presence of excess of chloride anion.
The results obtained\textsuperscript{57} were explained by competition of ionic and radical mechanisms, which lead to ‘Markovnikov’ and ‘anti-Markovnikov’ adducts, respectively. At this competition the nature of the unsaturated compound play an important role in determining the preferred mechanism. Thus, the major formation of ‘Markovnikov’ adducts and therefore the preference of the ionic mechanism in the series of olefins styrene $> 1$-methylcyclohexene $> 2,3$-dimethyl-1-butene $> 1$-heptene correlates with the ability of substituents to stabilize the intermediate carbenium ion.

Formation of the ‘anti-Markovnikov’ adduct points to the intermediacy of $\text{GeCl}_3$ radicals. Formation of the radicals is explained by one electron transfer in different ionic pairs and separation of the formed radical pairs without recombination. This one-electron transfer at the stage of trichlorogermane ionization is expected because of the low potential of $\text{GeCl}_3^-$ oxidation ($E_{1/2} = 0.48$ V) and was confirmed by examination of CIDNP in the reactions (see equation 19 below).

Reaction of trichlorogermane with 1-heptene (equation 15) to form 12 was studied most carefully\textsuperscript{57}. The authors believe that 1-heptene serves as an effective mediator in electron transfers and thus assists in the radical mechanism.

$$\text{Me(CH}_2)_4\text{CH}=\text{CH}_2 + \text{HGeCl}_3 \xrightarrow{-5{\degree}\text{C}} \text{Me(CH}_2)_4\text{CH}_2\text{CH}_2\text{GeCl}_3$$

Numbers attempts to obtain the ‘Markovnikov’ adduct by varying the reaction conditions, including its realization in concentrated HCl, had failed. Moreover, in a competitive reaction of a mixture of 1-heptene and styrene only the anti-Markovnikov adducts were formed for both olefins and, surprisingly, 1-heptene was found to be more reactive than styrene. This is also in agreement with the concept of two mechanisms. Here, 1-heptene assists in the formation of $\text{GeCl}_3$ radicals and styrene acts as a radical trap, forming selectively only the anti-Markovnikov adduct.

The radical pathway in the hydrogermylation of isobutene is confirmed by formation of the oligomer 13, whose structure also testifies to a dichlorogermylene participation (equation 16)\textsuperscript{57}.

Formation of oligomers with alternate olefin-$\text{GeCl}_2$ links is especially characteristic for etherates of trichlorogermane. Gradual addition of trichlorogermane to ether solution of an olefin or 1,3-diene at low temperature ($-20-70$ °C) is optimal for oligomer formation and in this case the yield of the oligomers is close to 100%. The molecular mass of the oligomers is not high, being 2000–6000\textsuperscript{60}.
B. Stereochemistry of the Hydrogermylation

The stereochemistry of the radical addition was studied in the reaction of trichloroger-
mane with 1-methylcyclohexene, which gives both 14 and 15 (equation 17).

\[
\begin{align*}
\text{Me} & \\
\text{1. } & \text{HGeCl}_3 \\
\text{2. MeMgBr} & \\
\text{(14)} & + \text{(15)}
\end{align*}
\]

\(\text{Me}^+\) NMR spectroscopy and a double resonance technique were applied for solving the stereochemical problem\(^5^7\). It was necessary to decide if the stereoisomer 14a or 14b is the product (Figure 2).

The spin–spin coupling constants of \(J(H^2H_e) = 3.8\text{ Hz}\) and \(J(H^2H_a) = 10.3\text{ Hz}\) strongly testify in favor of an axial position of \(H^2\). Having in mind the above mentioned constants, the third coupling constant \(J(H^1H^2) = 3.8\text{ Hz}\) was obtained from the ordinary NMR spectrum. This value serves as evidence for the equatorial position of \(H^1\), i.e. the structure corresponds to stereoisomer 14a. Thus, the radical addition of trichlorogermaine to 1-methylcyclohexene proceeds solely as an anti-addition with a diequatorial disposition of the entering groups.

The stereochemistry of the ionic addition was investigated in the reaction shown in equation 18\(^5^8\).

\[
\begin{align*}
\text{Me} & \\
\text{H}_a & \\
\text{H}_e & \\
\text{H}^1 & \text{GeMe}_3 \\
\text{H}^2 & \\
\text{Me} & \\
\text{H}^1 & \text{H}^2 & \text{COOMe} \\
\text{H}^1 & \text{GeCl}_3 & \text{D} & \text{COOMe} \\
\end{align*}
\]

A vicinal spin–spin coupling constant \(J(H^1H^2) = 2.4\text{ Hz}\) was obtained from the \(^1\text{H}\) NMR spectrum. This value indicates a threo-configuration of 16 that, in turn, supports a
stereospecific cis-addition of DGeCl₃ to the C=C bond of the ester. Such stereoselectivity is explained by a mechanism involving 'ion pairs'.

C. Chemically Induced Dynamic Nuclear Polarization in Reactions of Hydrogermylation

CIDNP effects were found in the reactions of trichlorogerme with styrene, 2-methyl-2-butene and 2,3-dimethyl-2-butene. Analysis of the CIDNP effects was carried out by the Kaptein rules⁶¹ and testifies for the radical participation in these reactions⁵⁹.

The integral character of the CIDNP effects show a considerable difference in the g-values of the radical pair partners. One of these partners is a germanium-centered radical and the other is a hydrocarbon radical.

\[
\begin{align*}
RR^1C\equiv CHR^2 + HGeCl_3 &\rightarrow RR^1C^+\underset{T}{\text{CH}_2R^2}\text{GeCl}_3^- \\
RR^1C^*\longrightarrow CH_2R^2\text{GeCl}_3^- &\rightleftharpoons RR^1C^*\longrightarrow CH_2R^2\text{GeCl}_3^+ \\
\text{diffusion in volume} &\rightarrow RR^1C^*\longrightarrow CH_2R^2, \text{GeCl}_3^* \\
HGeCl_3; RR^1C\equiv CHR^2 &\rightarrow RR^1C^*\longrightarrow CHR^2\text{GeCl}_3 \\
&\rightarrow RR^1CHCH_2R^2\text{GeCl}_3 + \text{GeCl}_3^* \\
\end{align*}
\]

It was assumed that protonation of the precursor olefin by trichlorogerme occurs in the first step with formation of ionic pair RR¹C⁺/CH₂R²/GeCl₃⁻ (equation 19, polarized molecules are doubly underlined). The following step is a single electron transfer with formation of a singlet radical pair. CIDNP effects appear as a result of singlet–triplet conversion in this pair. Since in the singlet pair metathesis occurs with formation of polarized precursor olefins and trichlorogerme, the CIDNP effects are observed in both the precursors and the final products.

Formation of polarized 'anti-Markovnikov' adducts here results from GeCl₃⁺ attack on the polarized olefin.

D. Reactions with Conjugated Dienes

Reaction of trichlorogerme with butadiene (equation 20) and isoprene leads to formation of cyclic and oligomeric compounds, together with the usual products of
hydrogermylation\[62\]. Formation of germacyclopentene \(18\) becomes predominant when the etherate of trichlorogermane is used whereas the yield of butenyltrichlorogermane \(17\) does not exceed 1–2\%\[27\]. The reaction seems to proceed by the GeCl\(_2\) participation mechanism, which was confirmed by model reactions of GeCl\(_2\)-dioxane\[63\]. The cyclic product \(18\) was found to form predominantly at higher temperatures, whereas the oligomeric product \(19\) is preferred at lower temperatures.

\[
\begin{align*}
\text{CH}_2\equiv\text{CHCH} &= \text{CH}_2 \quad \xrightarrow{\text{HGeCl}_3} \quad \text{CH}_3\text{CH} &= \text{CHCH}_2\text{GeCl}_3
\end{align*}
\]

(17) \hspace{1.5cm} (18) \hspace{1.5cm} (20)

Two possible mechanisms were taken into consideration: a concerted 1,4-cycloaddition and a 1,2-cycloaddition involving the intermediate formation of vinylgermacyclopropanes. In accordance with Woodward–Hoffmann conservation of orbital symmetry restrictions on the concerted mechanism, a 1,4-cycloaddition to give \(20\) and \(21\) proceeds in the case of 1,2-dimethylenecycloalkanes (equations 21 and 22), but not in cases of 1,3-cyclohexadiene and 1,3-cyclooctadiene.

\[
\begin{align*}
\text{GeCl}_2 \quad \text{dioxane} &\quad \xrightarrow{} \quad \text{GeCl}_2 \quad \text{dioxane} \\
\text{Cl} &\quad \text{Cl} \\
\text{Cl} &\quad \text{Cl}
\end{align*}
\]

(21) \hspace{1.5cm} (22)

The experimentally obtained value of the secondary kinetic isotope effect served as a strong argument in favor of a concerted mechanism involving conrotation or disrotation of terminal CH\(_2\) and CHD groups in 1,3-butadiene and 1,4-dideuterio-1,3-butadiene (equation 23)\[64\].

\[
\begin{align*}
\left[ \begin{array}{c}
\text{Ge} \\
\text{Cl} \\
\text{Cl}
\end{array} \right] \\
\text{or} \\
\left[ \begin{array}{c}
\text{Ge} \\
\text{Cl} \\
\text{Cl}
\end{array} \right]
\end{align*}
\]

(23)

The preference for a concerted 1,4-cycloaddition was also confirmed by theoretical calculations\[65,66\].
A concerted 1,6-cycloaddition of dichlorogermylene to cis-hexatriene resulting in 1,1-dichloro-1-germacyclohepta-3,5-diene (22) was found for the first time (equation 24)\textsuperscript{63,67}.

\[
\begin{align*}
\text{GeCl}_2 \text{ dioxane} & \quad \text{GeCl}_2 \text{ dioxane} \\
\text{GeCl}_2 & \text{GeCl}_2 \\
\end{align*}
\]

(22)

It is noteworthy that the product of a possible 1,4-cycloaddition of dichlorogermylene to hexatriene, i.e. 1,1-dichloro-2-vinyl-1-germacyclo-3-pentene, was not observed at all in the reaction mixture.

E. Reactions with \(\alpha,\beta\)-Unsaturated Carbonyl Compounds

Reactions of trichlorogermane with \(\alpha,\beta\)-unsaturated carbonyl compounds are widely used for synthesis of biologically active germanium sesquioxides\textsuperscript{8,68,69}, for example, for the synthesis of carboxyethylgermanium sesquioxide 24 via the adduct 23 (equation 25).

\[
\begin{align*}
\text{CH}_2=\text{CH}_2\text{COOH} + \text{HGeCl}_3 & \rightarrow \text{Cl}_3\text{GeCH}_2\text{CH}_2\text{COOH} \xrightarrow{\text{H}_2\text{O}} (\text{O}_{1.5}\text{GeCH}_2\text{CH}_2\text{COOH}_2) \\
\end{align*}
\]

(23) (24) (25)

The reaction seems to proceed by an ionic mechanism\textsuperscript{58}. An initial 1,4-addition can be proposed by analogy with the reaction of H\(^+\)SnCl\(_3\)\textsuperscript{\text{--}}, and this is followed by rearrangement to the product of formal 1,2-addition\textsuperscript{70}.

A new type of trichlorogermyl group/hydrogen replacement was found in the reaction of trichlorogermane with \(\beta\)-thienylacrylic acid (equation 26).

\[
\begin{align*}
\text{S} & \text{CH} \equiv \text{CHCOOH} \\
\text{HGeCl}_3 & \quad \Delta \\
\text{S} & \text{CHCH}_2\text{COOH} \quad \text{Cl}_3\text{Ge} \\
\text{Cl}_3\text{Ge} & \text{Cl}_3\text{Ge} \\
\text{S} & \text{CHCH}_2\text{COOH} \\
\text{HGeCl}_3 & \quad \text{excess} \\
\text{Cl}_3\text{Ge} & \text{Cl}_3\text{Ge} \\
\text{S} & \text{CHCH}_2\text{COOH} \\
\end{align*}
\]

(25) (26) (27)
20. Trichlorogermane, a new superacid in organic chemistry

The protodegermylation of adduct 25 to form 26 occurs under thermolysis. In the case of 27, hydrogermylation of the thiophene double bonds by action of excess of trichlorogermane occurs. The hydrogenative function of trichlorogermane was also marked in the reaction of alkoxybenzenes as shown below in Section VIII.

F. Reactions with Cyclopropane Derivatives

Cyclopropanes can be regarded as unsaturated compounds, but their ability to react with opening of the ring is limited to additions of halogens, acids and mercury oxide salts\(^7\) and to participation in the reaction of metathesis\(^7\). The reactions of cyclopropane derivatives with HGeCl\(_3\) confirm the superacidic character of the latter. Trichlorogermane adds easily to alkyl- and arylcyclopropanes to give linear products with high yield. As shown in equation 27 for the case of phenylcyclopropane, the exclusive formation of the \(\alpha\)-isomer can be explained by the strong stabilization inferred by the phenyl group on the intermediate carbocation.

\[
\begin{align*}
\text{Ph} & \quad + \quad \text{HGeCl}_3 & \quad \rightarrow & \quad \text{PhCHCH}_2\text{CH}_3 \\
& & \quad \text{GeCl}_3 & \quad (85\%) \\
\end{align*}
\]

In other cases such selectivity is absent. Two isomeric octyltrichlorogermanes are obtained in reaction of trichlorogermane with \(n\)-amylcyclopropane and 1-methyl-2-butylcyclopropane and three isomeric methyltrichlorogermylecyclohexanes are obtained in the reaction with norcarane\(^7\).

It is known that ketones, which are capable of aldol condensation, react with trichlorogermane in a particular way. First, an aldol condensation occurs and then trichlorogermane adds to the \(\text{C} = \text{C}\) double bond of the product of condensation\(^7\). However, in the case of methyl cyclopropyl ketone, the condensation does not occur and a single isomer derived from the ring opening reaction is formed with 65\% yield (equation 28)\(^7\).

\[
\begin{align*}
\text{C} & \quad \text{Me} & \quad + & \quad \text{HGeCl}_3 & \quad \rightarrow & \quad \text{Cl}_3\text{GeCH}_2\text{CH}_2\text{CH}_2 & \quad \text{C} & \quad \text{Me} \\
\text{O} & & & & & \text{O} & \quad (65\%) \\
\end{align*}
\]

The terminal position of the trichlorogermyle group is explained by a steric factor and an additional O \(\rightarrow\) Ge coordination.

In the reaction with spiroheptadiene, the unexpected compound 28 was isolated (equation 29)\(^7\). Its formation was a result of an anionotropic allylic rearrangement.

\[
\begin{align*}
\text{Et} & \quad \text{GeCl}_3 & \quad \rightarrow & \quad \text{Cl}_3\text{Ge} & \quad \text{Et} \\
\text{Cl}_3\text{Ge} & \quad \text{Et} & \quad \text{Cl}_3\text{Ge} & \quad \text{Et} \quad \text{(28)} \\
\end{align*}
\]

Migration of GeCl\(_3\) groups under the acidic action of trichlorogermane is a quite common phenomenon\(^\text{10}\).
VII. DOUBLE GERMYLATION

A. Discovery and Reactions

An example of double germylation was first discovered in the reaction of trichlorogermane etherate with allyl chloride, as shown in equation 30\(^7\). Product 29 with two GeCl\(_3\) groups was obtained together with the product of condensation.

\[
\begin{align*}
\text{CH}_2=\text{CHCH}_2\text{Cl} + \text{HGeCl}_3 & \rightarrow \text{CH}_2=\text{CHCH}_2\text{GeCl}_3 + \text{Cl}_2\text{GeCH}_2\text{CH(GeCl}_3\text{)}\text{CH}_2\text{Cl} \\
& (16\%) \quad (29) \quad (30) 
\end{align*}
\]

Propylene, 1-butene and cyclohexene can also lead to reactions of double germylation\(^7\). Later, unusual products of double germylation were obtained as the only monomeric products in reactions with ethylene and acetylene\(^8\). Thus, if trichlorogermane itself reacts with ethylene and acetylene by a simple hydrogermylation route, then bubbling of the gases through trichlorogermane etherate leads to formation of double germylation products 30 and 31 (equation 31)\(^8\).

\[
\begin{align*}
2\text{R}_2\text{O} \cdot \text{HGeCl}_3 & \rightarrow \text{Cl}_3\text{GeCH}_2\text{CH}_2\text{GeCl}_3 + (\text{Cl}_2\text{GeCH}_2\text{CH}_2 \cdots)_n \\
& (30) \quad (31)
\end{align*}
\]

Participation of dichlorogermylene was assumed to play the key role in these reactions, as shown in equation 32. Theoretical examination of the GeCl\(_2\) interaction with ethylene showed that formation of a three-membered cycle with a Ge-atom is energetically not profitable, and therefore asymmetric \(\pi\)-complex 32 could be the intermediate instead of germacyclopropane 33\(^6\). Recent computations (DFT, Gaussian 94) confirmed the formation and calculated the geometry of such a complex in detail\(^6\). The primary formation of 34 and 30 in commensurable amounts was confirmed by observing the Ge–H bond in the IR and NMR spectra of the reaction mixture after distillation and by the easy transformation of 34 to 30 under the reaction conditions\(^2,7,9\).

\[
\begin{align*}
\text{CH}_2=\text{CH}_2 + \text{GeCl}_2 & \rightarrow \begin{bmatrix}
\text{CH}_2 \cdots \text{CH}_2 \\
\text{Cl}_2\text{Ge}
\end{bmatrix} \quad \text{or} \quad \begin{bmatrix}
\text{CH}_2 \cdots \text{CH}_2 \\
\text{Ge} \\
\text{Cl} \\
\text{Cl}
\end{bmatrix} \\
& (32) \quad (33) 
\end{align*}
\]

\[
\begin{align*}
\text{Cl}_3\text{GeCH}_2\text{CH}_2\text{GeCl}_3 + \text{Cl}_2\text{HGeCH}_2\text{CH}_2\text{GeCl}_3 & \rightarrow \text{Cl}_3\text{GeCH}_2\text{CH}_2\text{GeCl}_3 \quad \text{Cl}_2\text{HGeCH}_2\text{CH}_2\text{GeCl}_3 \\
& (30) \quad (34)
\end{align*}
\]

It should be noted that tribromogermylane forms the product of double germylation Br\(_3\)GeCH\(_2\)CH\(_2\)GeBr\(_3\) in its reaction with ethylene even in the absence of ether\(^8\).
B. Double Germylation of 9-Me-Anthracene

A surprising example of a double germylation reaction was first found in the aromatic series. Addition of two GeCl₃ groups into 9,10-positions of anthracene and 9-methylantracene (MA) proceeds in the absence of ether, but require bubbling of air through the reaction mixture simultaneously with addition of trichlorogermane. It should be noted that addition of trichlorogermane to MA in inert atmosphere leads to high yield of 9-trichlorogermyl-9-methyl-9,10-dihydroanthracene. Moreover, hidden radical steps of the reaction were revealed by studying CIDNP effects (see Section VIII.F).

In the presence of air at 5 °C, reaction of HGeCl₃ with MA occurs in a different manner to give quantitatively the double germylation product trans-9,10-bis(trichlorogermyl)-9-methyl-9,10-dihydroanthracene (equation 33). A trans-configuration for this product was suggested on the basis of comparison with an authentic sample of the cis-isomer obtained alternatively. This configuration is not sterically hindered and its formation can be ascribed to any mechanism.

![Diagram of the reaction](image)

The hidden radical steps mentioned above in an inert atmosphere may indicate a radical mechanism of the reaction in the presence of air. It was assumed that the cation-radical [MA]⁺⁺ (formed by a direct oxidation of MA or by a secondary conversion of the σ-complex [MAH]⁺ and detected by UV-spectroscopy) can participate in the reaction. Regarding the detailed mechanism, numerous routes of the cation-radical [MA]⁺⁺ with two anions GeCl₃⁻ in the presence of air can give the double germylation product 35. Alternative mechanisms for the direct oxidation which form GeCl₃⁺ radicals of trichlorogermane must also be considered. Furthermore, the radicals can add to MA in the 9 and 10 positions one after another or via a preliminary formation of Ge₂Cl₆. Whereas this mechanism is attractive due to its simplicity, extensive data on hydrogermylation reactions of numerous unsaturated compounds (at conditions not excluding the presence of oxygen) are
The nature of the unsaturated compounds dictate the reaction pathway to a great extent, but it still remains unclear why a radical mechanism predominates in some cases and why a radical hydrogermylation may lead to a radical double germylation.

On raising the temperature from 5 to 80°C, the reaction in the presence of air does not stop with the formation of 35. Quantitative hydrolysis of the latter by water formed in reaction gives rise to the polycyclic compound 37 (equation 34).

\[
\begin{align*}
\text{MeGeCl}_3 + \text{GeCl}_3\text{H} & \xrightarrow{+ \text{H}_2\text{O}, 80^\circ\text{C}} \text{MeGeCl}_3\text{GeCl}_2\text{O} \\
& \downarrow \text{(34)}
\end{align*}
\]

Methylation of 37 by excess of MeMgBr and further work-up of the reaction mixture by dilute HCl lead to the monochloride 38. Repeated methylation of 38 results in the cis-isomer 39 of 36 (equation 35).

\[
\begin{align*}
\text{MeGeCl}_3\text{GeCl}_2\text{O} & \xrightarrow{1. \text{MeMgBr}, 2. \text{dilute HCl}} \text{MeGeMe}_3\text{GeMe}_2\text{Cl} \\
& \downarrow \text{(38)}
\end{align*}
\]

\[
\begin{align*}
\text{MeGeMe}_3\text{GeMe}_2\text{Cl} & \xrightarrow{\text{MeMgBr}} \text{MeGeMe}_3\text{GeMe}_3 \\
& \downarrow \text{(39)}
\end{align*}
\]
The crystal structures of 35–39 were characterized. Compound 38 is a single isomer according to the $^1$H NMR spectrum. This means that only one Ge–O bond in 37 was broken during methylation. Positions 9 and 10 for the Me and GeMe$_2$Cl groups in compound 38, respectively, were determined on the base of the molecular ion fragmentation pathway in the mass spectrum, in particular, the presence of an intensive $[\text{M–Me}_3\text{GeCl}]^+$ ion with $m/z = 307$. Such fragmentation is energetically feasible if both groups in positions 9 and 10 are cleaved synchronously, thus resulting in aromatization of the middle ring.

The methylated isomers 36 and 39 have different melting points and $^1$H NMR spectra. Since compound 39 was obtained from 37, which has a cis-configuration of the two germyl groups about the central cyclohexane ring, the structure of 39 was assumed to be that of a cis-isomer. Consequently, the trans-structure was assigned for compounds 35 and 36.

Antracene reacts with trichlorogermane at 5°C in the presence of air similarly to MA, giving 9,10-bis(trichlorogermyl)-9,10-dihydroanthracene 40 with yield close to 100% (equation 36).

\[
\begin{align*}
\text{Antracene} + 2\text{HGeCl}_3 + \text{O}_2 &\rightarrow 9,10\text{-bis(trichlorogermyl)-9,10-dihydroanthracene} \\
&\quad(40)
\end{align*}
\]

An additional aim of this section is to draw attention to the worthwhile reexamination of many reactions of trichlorogermane at conditions where small amounts of oxygen were added carefully to the reaction mixture. Another interesting point is to reexamine the classical superacid reactions under similar conditions.

Relevant examples are the different actions of the CF$_3$SO$_3$H superacid on dodecamethylruthenocene in inert atmosphere and in the presence of air\(^8\). Another example is the oxidation of methane with oxygen in concentrated sulfuric acid in the presence of Pt catalysts to form methanol derivatives\(^8\).

**VIII. REACTIONS OF HGeCl$_3$ WITH AROMATIC COMPOUNDS**

The uncatalyzed hydrogermylation reaction of aromatic multiple bonds by trichlorogermane was discovered in 1965 by two of the authors of the present review. The reactions between anisole, naphthalene and thiophene and HGeCl$_3$ were investigated in their works\(^32,8\).

The proposed mechanism of the reaction, shown in equation 37, involves the initial formation of $\pi$-complexes and subsequent protonation of the aromatic ring with the formation of $\sigma$-complexes.
The formation of π-complexes has been confirmed by a study of the NMR spectra of HGeCl₃ solutions in aromatic substrates. Upon such complex formation, the germyl hydrogen signal is observed to shift to higher fields, from 7.6 to ca 6.0 ppm, as a consequence of the effect of the magnetic anisotropy of the aromatic nucleus. Attempts to observe directly the intermediate σ-complexes in the reactions turned out to be unsuccessful owing to the low concentrations of these complexes and their short lifetimes. Indirect data on the formation of σ-complexes were obtained from experiments on deuterium exchange between DGeCl₃ and methylbenzenes. Deuterium exchange is the simplest electrophilic substitution reaction and its presence implies the formation of the corresponding σ-complexes (equation 38).

While deuterium exchange between DGeCl₃ and benzene and toluene does not occur at room temperature, trichlorogermane behaves as a strong acid with the more basic methylbenzenes, i.e., m-xylene, mesitylene and isodurene, by promoting rapid deuterium exchange. With mesitylene, for example, the equilibrium is established at 20 °C after 60 minutes.
Successful observation of the stable $\sigma$-complex in the case of trimethoxybenzene (see Section III.C) is another indirect confirmation of the reaction pathway.

Trichlorogermane does not react with phenyl halides and naphthyl halides. This is again indicative of the electrophilic nature of the interaction between trichlorogermane and the aromatic compounds.

The reactions of trichlorogermane with phenoxy- and alkoxybenzenes, methylbenzenes and condensed aromatics\textsuperscript{86,87} have been studied under different conditions and additional data concerning their mechanisms have been obtained.

A. Reaction with Anisole

A detailed study of the reaction between HGeCl$_3$ and anisole has revealed a strong dependence of the nature and ratio of the formed products on the conditions under which the reaction is carried out\textsuperscript{88}. The reaction between an excess of HGeCl$_3$ and anisole (a molar ratio of 3 : 1) at room temperature takes place most selectively (equation 39) and, over a period of 72 hours, leads to 1-methoxy-$\sigma$-1,3-$\tau$-1,3-trans-tris(trichlorogermyl)cyclohexane (42-$\tau$-cis,trans) in a yield of 82%. It has been established by using $^1$H NMR spectra that an intermediate compound is formed during the course of this reaction, and that its concentration attains a maximum value of 22% after 12 to 16 hours and subsequently decreases. This product, which is the double hydrogermylation product of anisole, 3-methoxy-3,5-bis(trichlorogermyl)cyclohexene 41, was isolated and identified in the form of the methylated derivative 43. Similarly, compound 42-$\tau$-cis,trans was converted to methylated derivative 44-$\tau$-cis,trans.

\[
\begin{align*}
\text{MeO} & \quad \text{MeO} & \quad \text{MeO} \\

\text{MeO GeMe}_3 & \quad \text{MeO GeMe}_3 & \\
(43) & \quad (44-$\tau$-cis,trans) & \\
\end{align*}
\]

This reaction takes place less selectively (equation 40) when anisole and HGeCl$_3$ are boiled together at 110 $^\circ$C. In this case, a cis,cis-isomer of the product of the exhaustive hydrogermylation of anisole is predominantly formed and isolated in the form of...
the methylated derivative 1-methoxy-r,1,3-cis,5-cis-tris(trimethylgermyl)cyclohexane, 45-cis,cis (23% yield). The (45-cis, cis) : (45-cis, trans) ratio in the mixture was 3 : 1.

\[
\text{MeO} \quad \text{MeO} \\

\]

\[
\begin{align*}
\text{MeO} & \quad \text{MeO} \\
\text{GeMe}_3 & \quad \text{GeMe}_3 \\
\text{MeGe} & \quad \text{MeGe} \\
\text{GeMe}_3 & \quad \text{GeMe}_3 \\
\end{align*}
\]

(40)

1-Methoxy-3,5-bis(trimethylgermyl)cyclohexane 46 (15% yield), 1-(4-methoxyphenyl)-r,1,3-cis-5-cis-5-tris(trimethylgermyl)cyclohexane 47 (20% yield) and also 3,5-bis(trimethylgermyl)cyclohexanone 48 (15% yield, ratio of cis- and trans-isomers 3 : 1) were isolated from the reaction mixture together with 45.

The formation of the hydrogenolysis and alkylation products together with the hydrogermylation products are common in the reaction of HGeCl₃ with aromatic compounds. We will encounter later such pathways of reaction in the reaction with diphenyl ether (see Section VIII. C).

A similar acid catalyzed reaction (equation 41), called hydrodimerization, was found for benzene and alkylbenzenes, which are converted over polyfunctional zeolite catalysts to phenylcyclohexane derivatives \(^{89}\).

\[
\text{H}_2, \text{zeolite catalysis} \quad \text{H}_2 \quad \text{zeolite catalysis}
\]

(41)
B. Reaction with 1,4-Dimethoxybenzene

As would be expected, the presence of a second electron-donating group in 1,4-dimethoxybenzene appreciably increases its rate of reaction with HGeCl₃ in comparison with anisole. With a threefold molar excess of HGeCl₃, the reaction at room temperature is complete after a period of 4 to 5 hours and leads to the formation of 1,4-dimethoxy-1,2,4-tris(trichlorogermyl)cyclohexane 49 in 85% yield (equation 42)²⁸.

\[
\text{MeO} \;
\begin{array}{c}

\text{MeO} \\
\text{GeCl₃} \\
\text{MeO} \\
\text{GeCl₃} \\
\text{MeO}
\end{array}
\]

(42)

The occurrence in 49 of bulky trichlorogermyl groups in a vicinal position and at geminal centers is the reason for its facile hydrogenolysis (protodegermylation) under the action of an excess of trichlorogermane at 80 °C (equation 43). The yield of 50 attained a value of 43%. 50 is converted with MeMgBr to 51.

\[
\text{MeO} \;
\begin{array}{c}

\text{MeO} \\
\text{GeMe₃} \\
\text{MeO}
\end{array}
\]

(43)

The treatment of 49 with an excess of MeMgBr in ether and subsequent hydrolysis of the product did not lead to the corresponding tris(trimethylgermyl) derivative but yielded a mixture of 4-methoxy-4-trimethylgermylcyclohexanone 52 (35%), 4-methoxy-1,4-bis(trimethylgermyl)cyclohexene 53 (17%) and 1,4-dimethoxybenzene (21%) (equation 44).

\end{array}
\]

(44)
C. Reaction with Diphenyl Ether

When HGeCl$_3$ is reacted with an excess of diphenyl ether 54 at 100–150 °C, the hydrogermylation of the aromatic multiple bonds is accompanied by another example of unusual alkylation reaction, which is shown in equation 45.\(^{90}\)

\[
\begin{align*}
\text{HGeCl}_3 \quad &\text{Cl}_3\text{Ge} \\
\text{O} \quad &\text{GeCl}_3 \\
\text{O} \quad &\text{GeCl}_3 \\

\text{analysis. The structure of 56 indicates that the reaction between HGeCl}_3 \text{ and diphenyl} \\
\text{ether must include three steps in which one of the benzene nuclei of the ether is exhaus-} \\
\text{tively germylated, the ether C—O bond is broken and the excess diphenyl ether is alkylated} \\
\text{in the \textit{para}-position by the carbenium ion formed upon the rupture of the C—O bond.} \\
\text{The first stage of this reaction was confirmed by us by isolating the product of} \\
\text{hydrogermylation 57 when the reaction was carried out under milder conditions at 20 °C} \\
\text{(equation 46).}
\end{align*}
\]
Fission of the C—O ether linkage in 57 with the formation of the ion pair 58 is then possible (equation 47). It is to be noted that the ability of HGeCl₃ to cleave the C—O bond in light ethers is well known.¹⁵

Finally, the carbenium ion moiety of the ion pair 58 alkylates the excess diphenyl ether in the *para*-position with respect to the phenoxy group, giving the final product 55. Hence, the catalytic alkylating function of HGeCl₃ in the Friedel–Craft reactions was established for the first time.

Such examples are rare because GeCl₃⁻ counterion, unlike the counterions of classical superacids, usually recombines with the carbenium ions with the formation of Ge—C bonds. In the present case, the ion pair 58 does not yield a stable recombination product and instead it participates in an intermolecular reaction. This is probably due to the fact that, for steric reasons, the recombination product with two geminal GeCl₃ groups is unstable at an elevated temperature.

Another mechanistic possibility involves a single electron transfer within the ion pair 58 with the formation of the corresponding radical pair 59 (equation 48), since the GeCl₃ substituent in 58 must *a priori* destabilize the carbenium center due to the negative I-effect.

---

¹⁵ The superscript number refers to the page number in the original text where this information is located.
In this case, the final alkylation step will naturally proceed by a radical substitution mechanism. One’s attention is drawn to the high overall yield (>70%) of 56, which implies that the selectivity of each step is not <90%.

The cyclohexane ring in 56 has a chair conformation with the three trimethylgermyl substituents in equatorial positions.

**D. Reaction with Triphenylamine**

The majority of aromatic amines (tribenzylamine, diphenylamine, \(N,N\)-diethylaniline) do not undergo hydrogermylation but form aminates with \(\text{HGeCl}_3\) which are inert to the action of an excess of \(\text{HGeCl}_3\). An exception is triphenylamine which, at room temperature, with \(\text{HGeCl}_3\) forms the unusual iminium salt, 3,5-bis(trichlorogermyl)cyclohexylidenediphenyliminium trichlorogermanate 1 (Section III.C).

A change in the conditions under which the reaction between triphenylamine and \(\text{HGeCl}_3\) is carried out leads to the formation of other products. For instance, when the temperature of the reaction is increased from 20 to 80 °C and there is a 4 to 5-fold molar excess of \(\text{HGeCl}_3\), the \(\text{cis-1}\), which is initially formed, is converted into the formal hydrogenation product 1-diphenylamino-3,5-bis(trichlorogermyl)cyclohexane 60, which is isolated with a yield of 53% in the form of the methylated derivative 61 (equation 49).

\[

\text{Cl}_3\text{Ge} \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \ Quad
E. Reactions with Benzene and Methylbenzenes

It was pointed out earlier that benzene and methylbenzenes do not add to $\text{HGeCl}_3$ under normal conditions although some of them do participate in deuterium exchange with $\text{DGeCl}_3$. The general hydrogermylation equation (equation 50) vividly reflects a sequence of heterolytic stages of exhaustive addition to the aromatic double bonds.

The stages controlling the reaction course are undoubtedly represented here by stages of $\sigma$-complex and cyclohexadiene derivative formation. We suggested that the protonating ability of $\text{HGeCl}_3$ could be increased by the addition of strong Lewis acids, thus making it sufficiently reactive with those aromatic compounds to which it is usually inert.

This operation is quite usual when modified sulfuric or hydrofluoric acids increase its $H_0$ value by the addition of such Lewis acids as $\text{SO}_3$, $\text{BF}_3$ or $\text{SbF}_5$. Indeed, it was found that in the presence of small amounts of $\text{AlCl}_3$ in a sealed glass tube at 70°C, benzene and toluene react during 3–5 days with $\text{HGeCl}_3$ according to the hydrogermylation scheme. The hydrogermylation is followed by alkylation, giving a complex mixture of isomeric products (equation 51).

\[
\begin{align*}
\text{Cl}_3\text{Ge} & \rightarrow \text{Cl}_3\text{Ge} \quad \text{GeCl}_3 \\
\text{Cl}_3\text{Ge} & \rightarrow \text{Cl}_3\text{Ge} \quad \text{GeCl}_3
\end{align*}
\]

(50)
However, not only the protonating ability of HGeCl₃ or systems derived from it determine the addition to aromatic carbon–carbon bonds, in contrast to the behavior of other HX acids. The specific features of HGeCl₃ are probably manifested at the step of the cyclohexadiene derivative formation. Energy is obviously lost during the conversion from σ-complex to cyclohexadiene. The formation of the cyclohexadiene–GeCl₂ molecular complex (the GeCl₂ present in the reaction mixture is a result of a well-known reaction, cf. Section III) is likely to be responsible for the equilibrium shift in the direction of the cyclohexadiene. It is likely that application of some other compounds which provide such shift by complexation with cyclohexadiene will enhance the addition of other HX acids to aromatic double bonds.

Finally, the application of pressure may speed up some steps and be advantageous. Indeed, it has been found that, under a pressure of 5 to 14 kbar, benzene and methylbenzenes react with HGeCl₃ quite readily\(^\text{92}\).

Mesitylene undergoes hydrogermylation the most readily and selectively. At a HGeCl₃ : mesitylene molar ratio of 2 : 1, the conversion of both compounds after 2 hours at 80°C and a pressure of 10 kbar is close to 100%. The corresponding cyclohexene \(\text{(62)}\) (equation 52) is the main product (yield 93%) of the double hydrogermylation. No products involving the addition of three molecules of HGeCl₃ were formed, even at significant excess of the latter.

![Diagram](attachment:diagram.png)

The two compounds \(\text{62}\) and \(\text{63}\) were isolated and characterized. As in the previously described examples, methylation of the chlorides by MeMgBr proceeded smoothly without any side reactions in which germyl groups are split off.

In the reaction between toluene or \(m\)-xylene and HGeCl₃ at 80°C and 5–10 kbar, depending on their molar ratio, isomeric cyclohexenes were also the main products of the double hydrogermylation (equation 53). These were isolated in the form of their methyl
derivatives 64 (overall yield 50%). Here, products 65 of the exhaustive hydrogermylation are also formed in small amounts (1–6%).

\[
\begin{align*}
\text{Me} & \quad \text{Me} \\
\text{R} & \quad \text{R} \\
\end{align*}
\]

1. HGeCl₃, 5–10 kbar
2. MeMgBr

\[
\begin{align*}
\text{Me} & \quad \text{GeMe₃} \\
\text{R} & \quad \text{GeMe₃} \\
\text{Me} & \quad \text{GeMe₃} \\
\text{R} & \quad \text{GeMe₃} \\
\end{align*}
\]

(64) up to 50%

(65) 1–6%

The reaction with benzene proceeds under the most drastic conditions. At a molar ratio HGeCl₃ : benzene = 2.5 : 1, a temperature of 140 °C and a pressure of 14 kbar, the degree of conversion of benzene did not exceed 70% after 6 hours. A complex mixture of products is formed among which, after treatment of the reaction mixture with an excess of MeMgBr in ether, the products 66, 67 and 68 of the double and complete hydrogermylation which are formed in very small yields were identified by using gas chromatography–mass spectrometry combination (equation 54).

\[
\begin{align*}
\text{Cl} & \quad \text{GeMe₃} \\
\text{GeMe₃} & \quad \text{GeMe₃} \\
\end{align*}
\]

(66) (67) (68)

A molecular mechanism is most likely for the addition of HGeCl₃ to methylbenzenes under a high pressure.
F. Reactions with Condensed Aromatics

Hydrogermylation of naphthalene\textsuperscript{79}, phenanthrene\textsuperscript{79}, anthracene and 9-Me-anthracene\textsuperscript{82} to form \textbf{69–71} proceed in the usual way, in accordance with equations \textbf{55–57}. Reactions with anthracene and 9-methylanthracene (MA) in benzene solution at inert atmosphere\textsuperscript{82} lead to a single isomer of 9-trichlorogermyl-9-methyl-9,10-dihydroanthracene \textbf{71} (R = Me) in close to quantitative yield. The structure of \textbf{71} shows that protonation takes place in the 10 position of MA in accordance with the orientation effect of the Me group, as happens in the reactions of MA with classical superacids which give a stable $\sigma$-complex\textsuperscript{93}.

\begin{equation}
\begin{array}{c}
R \\
\end{array} \quad \frac{HGeCl_3}{\text{HGeCl}_3} \quad \begin{array}{c}
R \\
\end{array}
\text{(69) 70–75\%}
\end{equation}

\begin{equation}
\begin{array}{c}
\end{array} \quad \frac{HGeCl_3}{\text{HGeCl}_3} \quad \begin{array}{c}
\end{array}
\text{(70) 90\%}
\end{equation}

\begin{equation}
\begin{array}{c}
\end{array} \quad \frac{HGeCl_3}{\text{HGeCl}_3} \quad \begin{array}{c}
\end{array}
\text{(71) ca 100\%}
\end{equation}

Some evidence of the reaction mechanism was obtained from the UV spectra. Dissolving MA in dry trichlorogermane at low temperature leads to an intensively blue $[\text{MA}]^{+}\cdot$ cation-radical. Generation of the intensively colored cation-radical MA$^{+}\cdot$ was ascribed to a secondary reaction of the weakly colored $\sigma$-complex $[\text{MAH}]^{+}$ with $[\text{MA}]^{94,95}$ (equations \textbf{58} and \textbf{59}).

\begin{equation}
\text{MA} + \text{HGeCl}_3 \leftrightarrow [\text{MAH}]^{+}\text{GeCl}_3^{-}
\end{equation}

\begin{equation}
[\text{MAH}]^{+} + \text{MA} \leftrightarrow [\text{MA}]^{+\cdot} + [\text{MAH}]^{+}\cdot
\end{equation}

The absorption maximum at 640 nm in the UV spectrum of the dark-blue solution of MA in trichlorogermane at $-70$ to $-90^\circ\text{C}$ belongs to the cation-radical $[\text{MA}]^{+\cdot}$ and disappears on raising the temperature when the reaction is over.
A surprising color effect has been observed due to a decrease in the mixture temperature when 1 ml of trichlorogermane reacts with a small yellow crystal of 9-Me-anthracene. When one such sample was allowed to freeze in liquid nitrogen without stirring, another sample was stirred energetically by a glass stick when freezing. The first sample remained colorless in solution after freezing, whereas the second one became black-blue because deeply-colored cation-radicals of 9-Me-anthracene were torn off the crystal.

The well-known literature ESR spectrum of the cation-radical$^9$ was not observed for the blue solutions of MA in trichlorogermane, probably due to the existence of [MA]$^{++}$ and [MAH]$^{++}$ in the poor electrolyte HGeCl$_3$ as a singlet pair. Attempts to observe absorption bands of the CH$_2$ group of the σ-complex by means of a diffused light version of IR spectroscopy had failed$^{22}$. Nevertheless, a CIDNP effect was observed in the reaction of MA with trichlorogermane when it was carried out in a resonance cell of an NMR spectrometer. The intensive positive integral CIDNP effect of the aromatic protons surely testifies in favor of hidden radical stages, some of which were observed experimentally$^9$.

It should be noted that when compound 71 (R = H) is treated with AlCl$_3$+ gaseous HCl, it loses HGeCl$_3$ and forms the arenium σ-complex 72 (equation 60)$^{22}$.

\[
\begin{align*}
\text{H} & \quad \text{GeCl}_3 & \quad \text{AlCl}_3 + \text{HCl} & \quad \text{CH}_2\text{Cl}_2 \\
\text{H} & \quad \text{H} \\
(71), \text{R} = \text{H} & \quad (72)
\end{align*}
\]

IX. CONCLUSIONS

Trichlorogermane, which is a well-known compound in organometallic chemistry, has been characterized as a new superacid in organic chemistry. This reagent has great potential, including its use as a new tool in investigating various aspects of carbenium ions.

The unusual superacidic properties of trichlorogermane are clearly manifested in its reactions with aromatic compounds. Here, the hydrogermylation of the aromatic nucleus is the basic pathway of the reaction between trichlorogermane and aromatic compounds. In many cases the reaction is accompanied by processes of protodegermylation, alkylation, trans–cis isomerization of the trichlorogermyl derivatives of cyclohexane and formation of some organic salts with GeCl$_3$– counterion.

The hydrogermylation of unsaturated compounds by trichlorogermane is an efficient new method for the synthesis of organogermainian derivatives of different classes. Replacement of germyl groups in these compounds with other functional groups is still a challenging task, which may be regarded as potentially important in fine organic synthesis.

Finally, the unusual behavior of trichlorogermane is a reason to seek analogy between classical superacids.

I. INTRODUCTION

When compared to the photochemistry of organosilicon compounds, the photochemistry of the organometallic compounds of the heavier elements is less well developed. However, the importance of studying the photochemistry of these systems stems from significant differences between their photochemical behaviour and that of their more common silicon analogues. For instance, studies on mixed metal systems have demonstrated a considerable difference between the thermal stability of germylene versus silylene intermediates, which can have a dramatic effect on the final product distribution of photochemical reactions. Furthermore, the need to develop new processes for the generation of high-purity metal films of these elements highlights the need for a fuller understanding of their photochemical properties. Consequently, while the available literature on the photochemical
properties of Ge, Sn and Pb compounds is relatively limited, it still represents an important resource worthy of periodic review.

We have organized this review of the photochemistry of organometallic compounds of the heavier group 14 elements by compound class, with the exception of photoinduced electron transfer processes which we treat under a separate heading. This review describes the recent literature which has appeared since the publication in 1995 of an earlier review of this topic.

II. SATURATED OLIGOMERIC SYSTEMS

A. Homometallic Systems

The direct photolysis, by low-pressure Hg arc output, of permethylated linear polygermanes Me(Me₂Ge)ₙMe (n = 3 to 6) has been investigated in cyclohexane solution. The photoproducts were analysed by GC-MS techniques and their mechanisms of formation probed by use of trapping agents such as CCl₄ or dienes. Studies conducted in the presence of CCl₄ produced polygermyl chlorides in high yield, confirming that homolytic cleavage of the germanium–germanium bond is an important photochemical event. Photolyses in the presence of 2,3-dimethyl-1,3-butadiene (DMBD) produced only low yields of the expected germylene trapping product, 1,1,3,4-tetramethyl-1-germacyclopenta-3-ene, indicating that while germylene species are produced, it is only with low efficiency. The ultimate products of the photochemistry are lower-order polygermanes as outlined in Table 1, while Table 2 contains the products and yields obtained in the trapping experiments. These results are consistent with a mechanism involving both homolytic cleavage of the Ge–Ge bond and germylene formation (Scheme 1).

<sup>a</sup>1,1,3,4-Tetramethyl-1-germacyclopent-3-ene.

<sup>b</sup>Room-temperature photolysis for 5 hours.

<sup>c</sup>Room-temperature photolysis for 1 hour.
Me$_3$CSiMe$_2$GeMe$_2$SnMe$_3$ was reported$^3$, and can be understood in terms of the three reaction types in Scheme 2. These involve photoelimination of either dimethylgermylene or dimethyl stannylene or cleavage of the Ge–Sn bond to form radicals. All of these products were detected by GC-MS techniques. Interestingly, experiments on this compound, which were conducted in the presence of trapping agents for either stannylene or germylene (Ph$_3$GeH, Et$_3$SiH, Me$_3$GeH, n-Bu$_3$SnH, DMBD or dimethyl disulphide), did not produce the expected trapping products. Furthermore, the product distribution obtained did not vary significantly from that observed in the absence of trapping agents, apart from the apparent quenching of the radical pathway. It would appear that radical generation may interfere with the ability of the trapping agents to react with the germylene and stannylene species. Similar observations have been reported for other R$_2$Ge$^••$ species, which suggests that such intermediates are capable of electron transfer processes producing ion-based chemistry$^4$.

**SCHEME 2**

**III. ALKYL COMPOUNDS**

Metalloalkyl compounds of the heavier group 14 elements are used as precursor sources in the deposition of thin metallic films for use in the electronics industries$^5,6$. Photoinduced dealkylation is potentially a very useful technique in the deposition of metals from the gas phase, although in general such films contain high concentrations of carbonatious components. Photodealkylation of alkylgermanium compounds using UV photons can be problematic because of the opaque nature of the germanium films produced. This inhibits further film growth. One possible solution to this problem is to use infrared photons with suitable sensitzers, to effect the dealkylation reaction. The germanium film, being transparent in the infrared region, would not act as a self-filter for further film growth. Mixtures of tetramethylgermane and sulphur hexafluoride (as sensitizer) were irradiated with the output of a CO$_2$ laser, the nature of the gaseous products being determined by mass spectrometry$^7$. The principal gaseous products formed were ethane, ethene and ethyne. A gray solid deposit was assumed to be germanium.

Deposition of germanium films from the liquid phase has also been achieved$^8$. In this work a series of organogermanes compounds were used including those containing methyl, vinyl, ethyl, propenyl, allyl and phenyl substituents. Dodecane was used as the solvent. Backscattering analysis of the deposited germanium film following ArF excimer irradiation confirmed that it consisted exclusively of germanium with no evidence of organic contaminants.

**IV. ARYL COMPOUNDS**

Aryldisilanes have been the subject of numerous photochemical investigations over many years$^9$. In general, photolysis of this class of compound produced three distinct
intermediate types, cyclic or acyclic silenes or silyl radicals (Scheme 3). The formation of the silene species is thought to derive from a singlet excited state, while a triplet state has been implicated in the formation of the free radicals. UV-monitored flash photolysis has been used to probe the chemistry of a range of reactive intermediates produced from these precursors. The photochemistry of 1,1,1-trimethyl-2,2,2-triphenyldisilane has proved particularly useful in identifying the cyclic silene, 1-silahexatriene species (1), as an important intermediate species, by permitting the isolation of its ketone adducts.

**Scheme 3**

This study has been extended to include the mixed silane-germane and the digermane systems Ph$_3$SiGeMe$_3$, Ph$_3$GeSiMe$_3$ and Ph$_3$GeGeMe$_3$. Photolysis of these materials produced transient absorptions in the 330–335 nm range and also an absorption centred at approximately 490 nm. The former absorption was assigned to the silyl or germyl radical species on the basis of band positions and the fact that they are quenched by chloroform with a rate constant ($1.7 \times 10^8$ M$^{-1}$ s$^{-1}$) which agrees with published values for the reaction of these radicals with CHCl$_3$. The latter absorption, which previously was assigned to Ph$_2$Ge, is now thought to correspond to the substituted (1-germa)hexatriene (2).

**V. CONJUGATED CATENATES**

Systems which contain $\sigma$(E-E)-$\pi$ conjugated systems (E = Si or Ge) have been the subject of many photochemical investigations. For the most part investigations have focussed on silicon systems, that first identified carbon–silicon double-bonded species as photoproducts. Later studies also indicated that arylsilanes undergo 1,3-sigmatropic shift reactions as well as extrusion processes yielding silylenes. ESR studies have
identified silyl radicals following photolysis of Si—Si bonded species, and the range of photoproducts formed was rationalized in terms of a radical pair mechanism\textsuperscript{21}. Furthermore, the results of flash photolysis experiments also suggest a radical pair mechanism in the photochemistry of arylgermanes\textsuperscript{22}.

The photochemistry of furylated catenates of the group 14 elements has been reported\textsuperscript{23}. Irradiation of 2-(pentamethyldisilanyl)furan and 2-(pentamethyldigermanyl)furan in alkane solution under a variety of conditions yielded the products as outlined in Table 3, which were identified by GC and NMR spectroscopy. These data indicate differences in the behaviour of the germanium system when compared to the silicon. For instance, photolysis of 2-(C\textsubscript{4}H\textsubscript{3}O)Si\textsubscript{2}Me\textsubscript{5} in the presence of \textit{t}-BuOH produced significant quantities of the \textit{t}-butoxide product, while similar photolysis of the analogous germanium compound did not. Also, the yield of chloro-compounds was significantly lower for the germanium system than for the silicon. Failure to observe butoxide products in the photolysis of the germanium compounds has been explained by proposing that the germyl radicals, unlike the silyl analogues, do not undergo the expected disproportionation reaction (Scheme 4)\textsuperscript{24}. However, the presence of 2-(C\textsubscript{4}H\textsubscript{3}O)EMe\textsubscript{3} (E = Si or Ge) in the photosylate does imply the generation of dimethylsilylene and dimethylgermylene in these systems. While photolysis of 2-(C\textsubscript{4}H\textsubscript{3}O)Si\textsubscript{2}Me\textsubscript{5} in the presence of triethylsilane, a known trapping agent for silenes, generates triethylsilyldimethylsilane, photolyses in the presence of trapping agents for germenes (2-methyl-1,3-butadiene or 2,3-dimethyl-1,2-butadiene) failed to yield the expected germacyclopentadiene products (Table 3).

$^a$Not quenched.

$^b$Signal too weak for reliable kinetic analysis.
following photolysis of both 2-(C₄H₃O)Si₂Me₅ and 2-(C₄H₃O)Ge₂Me₅. The 310 nm feature consisted of two components one with a half-life of 2–3 µs, and a second with a half-life of approximately 40 µs. The shorter-lived species were assigned to the furyl-substituted silyl and germyl radicals, based on their spectral characteristics and reactivity towards added quenching agents (see Table 4), which are consistent with rate constants measured for related systems²². These decayed following first-order kinetics, suggesting that the radical species were reacting either with the solvent or alternatively with the parent compound. The nature of the longer-lived species remains somewhat uncertain but is likely to be associated with the long-lived component of the absorption between 370–380 nm. This absorption also has two time-resolved components with half-lives of 1.6 µs for the silicon system and 0.8 µs for the germanium. The long-lived component has a half-life similar to that of the long-lived species absorbing at shorter wavelengths. Interestingly, and as outlined in Table 4, the short-lived species generated from the silicon system was not quenched by either CCl₄ or EtOH. However, the equivalent species obtained from the germanium precursor was quenched by both CCl₄ and DMBD, although the signals were too weak to provide reliable kinetic parameters.

It is clear from these experiments that the primary photochemical process for these group 14 catenates is homolytic cleavage of the E/NUL E bond (Scheme 4). In chlorinated solvents the radicals formed abstract a chlorine atom, yielding the corresponding chlorides. However, the observation of relatively large yields of hydrosilanes was in direct contrast to the absence of hydrogermanes, which points to a significant difference in the reaction mechanisms for the two systems. In particular, the disproportionation reaction to produce silenes and hydrosilanes was favoured while this reaction was not significant for the germanium system. In contrast, the germyl radical pair either abstracts a hydrogen atom from the solvent or couples at the ipso-position, producing the diradical as an important reaction path.

VI. METAL OXANES

A series of trapping experiments coupled with flash photolysis techniques has been used to study the photochemistry of digermoxanes²⁶. In general, the photochemistry of these systems is characterized by the homolytic cleavage of the germanium–oxygen bond producing germyl and germoxyl radicals. The photochemistry of a range of aryl-substituted digermoxanes and cyclic germoxanes has been reported. Photolysis of the digermane compounds in alkane solution using a low-pressure mercury lamp produced polymeric materials of moderately high weight averaged molecular mass (typically 1 x 10² to 9 x 10² a.m.u.). Elemental analysis of the polymers confirmed that they contained germanium atoms. Flash photolysis experiments using an excitation wavelength of 266 nm resulted in a transient species with absorptions in the region 300–400 nm. In the case of (Ph₂MeGe)₂O and (Ph₃Ge)₂O, two features were observed in this region, while (PhMe₂Ge)₂O yielded only one, although it appeared to consist of two unresolved components. For the diphenyl and triphenyl derivatives, the high-energy feature was assigned to the appropriate germyl radicals. They compare well with the germyl radical spectrum obtained by hydrogen abstraction from Ph₃Me₃–nGeH²⁷,²⁸, where the λ_max of the transient absorption spectrum for Ph₃Me₃–nGe was reported at 315, 330 and 332 nm respectively for n = 1, 2 or 3. These transient features decayed with second-order kinetics, which suggests that they were undergoing dimerisation presumably to form digermane species. They were also quenched by the addition of carbon tetrachloride, oxygen and dimethyl-1,3-butadiene as expected for germyl radicals (equation 1). These results are summarized in Table 5. Interestingly, the quenching of these absorptions resulted in a build-up of the longer-wavelength absorptions, indicating that the germyl radicals react...

with oxygen, yielding the species that absorb at longer wavelengths. Consequently, these long-wavelength absorptions can be assigned to germoxy radicals (equation 2), which decayed following second-order kinetics to give digermyl peroxides (equation 3).

\]

**VII. PHOTOINDUCED ELECTRON TRANSFER**

Compounds that contain heavier group 14 to group 14 or group 14 to carbon bonds can act as excellent electron donors. These bonds are subject to cleavage by various organic electrophiles, and because of their low ionization potentials they undergo efficient electron transfer reactions at rates limited only by the rate of electron transfer from the group 14 compound. Such reactions have received considerable attention for silicon–silicon systems, but those of the heavier elements such as germanium or tin have been less well studied. Photoinduced electron transfer reactions can also lead to interesting chemistry, including chlorinative cleavage of the metal–metal bonds in group 14 catenates. For instance, the germanium–germanium bond in a range of permethyloligogermanes can be oxidatively cleaved in the presence of only catalytic amounts of π-acceptors. The low ionization potentials (IPs) of permethyloligogermanes means that they are susceptible to donor–acceptor interactions, which can ultimately lead to electron transfer processes. Irradiation of octamethyltrigermane in CCl_4–MeCN mixtures (1:430 by volume) using the visible output of a high-pressure Hg arc lamp in the presence of a range of π-acceptor molecules produced Me_3GeCl, Me_5Ge_2Cl and Cl_3CCCl_3 in varying yields. These results are summarised in Table 6. The efficiency of conversion to products is directly proportional to the electron affinity of the acceptor species. Quenching experiments on the fluorescence of the acceptors confirmed that electron transfer was occurring, but at a rate below the diffusion-controlled limit (Table 7).

The proposed mechanism for the chlorinative cleavage involves the initial excitation of the acceptor to its lowest-energy singlet state. Electron transfer to the permethyloligogermane produces initially the radical anion of the acceptor and the radical cation of the...
germane. The oligogermane then undergoes spontaneous scission forming Me(Me₂Ge)₃⁺ and Me(Me₂Ge)ₙ₋ₚ⁺, which abstracts a chlorine atom from the CCl₄ solvent producing Me(Me₂Ge)ₙ₋ₚCl and CCl₃⁺, which ultimately dimerises yielding (CCl₃)₂. The cationic species is reduced by the acceptor radical anion yielding Me(Me₂Ge)ₙ⁺ and finally Me(Me₂Ge)ₙCl by abstraction of a further chlorine atom from the solvent. In contrast to studies on the silicon analogues, there appears to be little selectivity between the terminal and internal metal–metal bonds in the germane compounds, however.

Photoinduced electron transfer processes are also responsible for the carbon–carbon bond formation in fullerene systems. The use of photoexcited C₆₀ as an acceptor expands the range of functionalization chemistry for this material. The addition of silyl acetals to the triplet excited state of C₆₀ occurs efficiently, yielding the fullerene with ester functionality. The asymmetric allylic stannane Me₂CDCHCH₂SnBu₃ has also been shown to add to C₆₀ to yield exclusively C₆₀-1,2-CH₂CH-CDMe₂, in which the allylic group is introduced at the α-position, and no γ-adduct is formed. Such regioselective addition of Me₂CdCHCH₂SnBu₃ has also been reported for the photoreduction of the methylacridinium ion by photoinduced electron transfer from Me₂CDCHCH₂SnBu₃ to the singlet excited state of the methylacridinium ion. The γ-adduct is exclusively formed under thermal conditions, however. A possible explanation for this is that, in the electron transfer reaction, the Sn–C bond is significantly lengthened in the radical cation before the C–C bond formation. This leads to a more favourable α-addition because of the greater steric constraints of the two methyl groups on the γ-position.

The ability of Sn(IV) organometallic compounds to act as both electron donors or acceptors has resulted in their use in photochromic systems. Addition of 2-aminomethylpyridine to a solution of Sn(n-Bu)₄ₓₙX₄₋ₓ (X = CH₃COO, Cl or F) results in the formation of a deeply coloured solution, possibly the result of complex formation or, more likely, the formation of a charge-transfer complex. Irradiation of the solution efficiently bleaches the colour, which then recovers upon heating.
The addition of alkynes to disilenes and digermenes to yield disilacyclobutenes and digermacyclobutenes is thought to proceed by a stepwise mechanism involving either radical or zwitterionic intermediates. The photochemical generation of germasilenes from cyclo-SiGe$_2$Mes$_6$ (Mes = 2,4,6-trimethylphenyl) offers the opportunity to investigate the regioselectivity of this class of reaction$^{39}$. Initial photolysis of cyclo-SiGe$_2$Mes$_6$ results in the extrusion of Mes$_2$Ge••, which can be trapped by added HSiEt$_3$ (equation 4). The germasilene may then undergo cycloaddition with added alkynes. For example, photolysis of Si,Si-di-$t$-butyltetramesitylgermasilene in the presence of phenylacetylene produced a silagermacyclobutene compound and the 1,4-digermine as indicated in Scheme 6. The 1,4-digermine was formed by the reaction of the phenylacetylene with dimesitylgermylene, while reaction with the silagermene produced the silagermacyclobutene. Hydrolysis of the dimetallacyclobutene with aqueous base cleanly produced compound 3, confirming that the addition of phenylacetylene to germasilenes is regioselective and that the phenyl substituent is located $\alpha$ to the germanium atom.

\]

VIII. METAL–METAL MULTIPLE-BONDED SYSTEMS
Addition of methyl-Grignard reagents across the double bond in germasilenes was also investigated\textsuperscript{40}. Unlike the thermal chemistry of these systems, their photochemistry is reasonably straightforward. Again cyclo-SiGe\textsubscript{2}Mes\textsubscript{6} is used as a source of the germasilene and (Me\textsubscript{3}Si)\textsubscript{3}SiH was used to trap Mes\textsubscript{2}Ge. Two products were identified as presented in equation 5, which demonstrates that the methyl group adds regioselectively to the silicon end of the germasilene. The source of the siloxy groups remains uncertain; however, oxidation of the HSi(SiMe\textsubscript{3})\textsubscript{3} is a likely possibility.

**IX. SYSTEMS INVOLVING TRANSITION METAL FRAGMENTS**

The photochemistry of oligosilyl derivatives of the (η\textsuperscript{5}-C\textsubscript{5}H\textsubscript{5})Fe(CO)\textsubscript{2} (Fp) system has been extensively investigated\textsuperscript{41}. The primary photoprocess involves loss of CO, followed by α-elimination to form silyl(silylene) species, Fp(=SiR\textsubscript{2})(SiR\textsubscript{3}) (equation 6, E,E\textsuperscript{'} = group 6 element). Subsequent 1,3-alkyl, aryl and silyl migrations, isomerizations and silylene expulsions yield a complex range of products. The bimetallic disilyl complex FpSiMe\textsubscript{2}Me\textsubscript{2}SiFp when irradiated yielded all isomers of the silylene-bridged diiron complexes, Fp\textsubscript{2}(\mu-SiMe(SiMe\textsubscript{3})(\mu-CO), while prolonged photolysis produced the bis(silylene)-bridged species Fp\textsubscript{2}(\mu-SiMe\textsubscript{2})\textsubscript{2}\textsuperscript{42}. Again these reactions proceed following equilibration of silyl(silylene) intermediates.

\[
\text{hv}/-\text{CO} \xrightarrow{\text{CO}} \text{Fe} \quad \text{Me}_2 \quad \text{E} \quad \text{E}'\text{Me}_3 \\
\text{OC} \quad \text{Fe} \quad \text{Me}_2 \quad \text{E} \quad \text{E}'\text{Me}_3 \\
\text{OC} \quad \text{Fe} \quad \text{E}'\text{Me}_3 \\
\text{OC} \quad \text{Fe} \quad \text{E}'\text{Me}_3
\]
To investigate the effects of different group 14 elements on the stability of the coordinated silylenes, a range of systems was investigated including FpSiMe₂GeMe₂Fp, FpGeMe₂SnMe₃ and FpSnMe₂GeMe₃⁴³. Initial photolysis of FpSiMe₂GeMe₂Fp, with the output of a medium pressure mercury lamp filtered through Pyrex, was followed by both ¹H and ²⁹Si NMR spectroscopy. The three geometric isomers containing both bridging CO and germylene groups (Scheme 7) were observed as principle products with only trace amounts of the silylene–germylene bridged products. No evidence was obtained for the formation of the (µ-CO)(µ-SiMeGeMe₂) species. These results are consistent with those observed for the FpSiMe₂SiMe₂Fp system (see above); however, prolonged irradiation resulted in the quantitative formation of the silylene–germylene isomers. The observed products are explained in terms of the general mechanism outlined in Scheme 8. The exclusive formation of the germyleyne-bridged intermediate strongly suggests that the equilibrium between the germylene and silylene intermediates greatly favours the germylene species (Species A in Scheme 8). This conclusion is further supported by studies on tungsten germyl silyl systems⁴⁴.

Irradiation of FpGeMe₂SnMe₃ produced FpGeMe₃ and FpSnMe₃ formed in a 60 : 40 ratio (see Scheme 9), indicating that the stannylene intermediate is marginally favoured
SCHEME 9
21. The photochemistry of organometallic compounds of germanium, tin and lead over the germynene isomer. Perhaps of more interest was the observation of the isomerization product FpSnMe₂GeMe₃. However, photolysis of FpSnMe₂GeMe₃ failed to produce any FpGeMe₂SnMe₃. The possibility that the isomerization occurred by the insertion of SnMe₂ into FpGeMe₃ was ruled out by experiments conducted in the presence of stannylen traps. Consequently, it is proposed that the isomerization occurs subsequent to 1,3-methyl migration in the (stannyl)germylene iron intermediate (Scheme 9).

The photochemistry of oligosilyl systems containing the \((\eta^5-C_5H_5)Fe(CO)_3(Fp)\) moiety directly bonded to a silicon atom has been extensively investigated\(^{45}\). Following the photochemical expulsion of one CO ligand, the resulting intermediates undergo silyl-shift reactions producing silylene species, which in turn can eliminate silylene (Scheme 10). Silylgermyl or germysilyl analogues were also studied, but in these systems the germynene intermediate was formed preferentially and it was the subsequent chemistry of this intermediate that predominates (Scheme 11)\(^{46}\). The photochemistry of higher-order oligomeric systems has also been investigated. While the

![Scheme 10](image1)

![Scheme 11](image2)
SCHEME 12
tetrasilyliron complexes Fp(SiMe2)3SiMe2Ph undergo clean photochemical rearrangement to FpSi(SiMe3)2(SiMe2Ph), the photochemistry of the oligosilylgermyl systems is more complex. In these systems the photointermediates rearrange to yield products containing Fe–Ge bonds, reinforcing earlier observations that Fe–Ge bonds are more stable than their Fe–Si analogues, and are thus favoured when a dynamic equilibrium between them is possible. The two complexes FpSiMe2SiMe2GeMe2Ph and Fp*SiMe2SiMe2GeMe2Ph [Fp* = (η5-C5Me5)Fe(CO)3] rearranged cleanly to produce the single product FpGe(SiMe3)2(SiMe2Ph) or Fp*Ge(SiMe3)2(SiMe2Ph). The multi-step mechanism for this reaction is outlined in Scheme 12.

I. SCOPE AND LIMITATIONS

The development of new materials is closely associated with the civilization of mankind but only nowadays research focusing on all kinds of potentially new materials is called ‘materials science’. A new compound should be classified as a material when it is used in some sort of technical application or when at least it is potentially useful for a technical process. The number of organometallic polymers and supramolecular organometallic compounds which fulfill these requirements are still relatively rare, although there is a steadily increasing interest in so-called inorganic and organometallic polymers. Several review articles have been written to focus on several aspects of synthesis, structure and properties of inorganic and organometallic polymers. In the family of Group 14 element-containing polymers, silicon has received most attention and materials such as silicones have become important industrial products. The total quantity of silicones produced worldwide was estimated at approximately $1.3 \times 10^6$ tons in 1995. Organometallic polymers in which the heavier Group 14 elements germanium, tin and lead are incorporated in significant amounts have not entered the stage of industrial applications yet, but there is growing interest in such inorganic–organic polymers for which a modification of chemical and physical properties are to be expected and these compounds should give access to potential applications in diverse areas of industrial chemistry. For example, polystannanes might be used in photoresists for microlithography, polymer-supported organotin hydrides might be economically and ecologically useful reducing agents in organic synthesis and selected coordination polymers might be used as molecular sieves or solid catalysts.

The scope of this review includes three areas of germanium-, tin- and lead-containing polymers, namely polymetallanes, polymer-supported organoelement compounds and organometallic coordination polymers. The article is limited to those systems in which at least one Group 14 element–carbon bond is present. Thus, the large number of publications dealing with (i) inorganic germanium, tin and lead compounds embedded into an organic polymer matrix and, in addition, (ii) the use of inorganic and organometallic compounds as Lewis-acidic catalysts for the preparation of organic polymers are not the subject of this article. The literature mainly covers the years 1995 to the mid-2000, but selected work published earlier is included in order to give a comprehensive review.

The objectives of this article are (i) to give an overview on the compounds prepared mainly during the last five years, (ii) to compare synthetic routes, (iii) to discuss the structures and some structure–property relationships and (iv) to highlight important future directions for organometallic polymers containing germanium, tin and lead, respectively.
II. ORGANOMETALLIC POLYMERS CONTAINING TIN AND GERMANIUM IN THE BACKBONE

A. Polymetallanes

Currently, there is growing interest in polymers the frameworks of which are constructed from the Group 14 elements silicon, germanium and tin. Several reviews on polysilanes have appeared in the literature. In the first section of this article we focus on recent developments in the chemistry of polygermanes and polystannanes. The chemistry and structure–property relationship of oligostannanes and low molecular weight polystannanes was the subject of earlier reviews.

Formally, linear polymetallanes of the general formula \( R(MR_2)_nR \) \((R = \text{alkyl, aryl}; M = \text{Ge, Sn})\) can be viewed as structural analogues of polymeric hydrocarbons \( R(CR_2)_nR \). However, the electronic properties of polymetallanes do not resemble those of saturated hydrocarbon polymers, but show similarities to those of unsaturated conjugated polyenes. Theoretical and experimental studies have demonstrated that in oligo- and polymetallanes an intense low-energy absorption maximum occurs, which shifts to higher wavelengths with increasing chain length. This unique feature results from a so-called ‘\( \sigma \)-delocalization’ along the molecular backbone of the polymetallanes and has prompted Adams and Dräger to suggest the term ‘molecular metals’ for organopolystannanes with long chains. In Section II.A.1 below we describe the synthesis and characteristic physico-chemical features of polygermanes, and in Section II.A.2 the syntheses and properties of polystannanes are reported.

1. Polygermanes

a. Introduction. Syntheses, structures, properties and potential applications of polysilanes have been extensively studied, but their heavier analogues have received limited attention. The general characteristic properties of polysilanes and polygermanes are very similar, but the increased atomic size of germanium and the increased Ge–Ge bond length influence the \( \sigma \)-conjugation in the polymer backbone. Theoretical studies on the electronic properties of polygermanes were carried out. It was shown that the band gap \( E_g \) decreases in the order Si > Ge > Sn, which is the result of the lengthening of the corresponding element–element bonds. A synthetic drawback for the use of germanium-containing polymers is the lack of cheap commercial sources for germanium precursors. However, in 1985 Trefonas and West described the preparation of the first soluble high molecular weight germanium homopolymer and of some silicon–germanium copolymers starting from \( n\)-Bu\(_2\)GeCl\(_2\). In this section recent developments in the preparation of high molecular weight polygermanes are reported and the properties of polygermanes are discussed.

b. Syntheses. i. Wurtz-type coupling. In analogy to the most common preparation of polysilanes, the first polygermane (I) was prepared by the reductive coupling of \( n\)-Bu\(_2\)GeCl\(_2\) with sodium metal ( Scheme 1). Poly(dibutyl)germane prepared by this method shows a bimodal broad molecular weight distribution and molecular weights higher than \( 7.7 \times 10^5 \) were obtained. Mochida and Chiba carried out Wurtz-type coupling reactions of a range of dichlorogermanes under various conditions ( Table 1).

The poly(dibutyl)germane, as obtained by heating at reflux in toluene a mixture of dibutylchlorogermaine and sodium metal dispersion as reducing agent, had a narrow molecular weight distribution, but was relatively low in molecular weight (entry 1). The addition of 18-crown-6 ether to the reaction mixture gave even lower yields and decreased molecular weights (entry 3). By adding the sodium metal dispersion to a

\(^e\)An accurate molecular weight distribution was not determined.

toluene solution of \(n\)-Bu\(_2\)GeCl\(_2\) (inverse addition), lower yields of lower molecular weight polymers were obtained (entry 2). A similar observation was reported by Miller and Sooriyakumaran\(^{32}\). The addition of small amounts of HMPA as a co-solvent in the Wurtz-type coupling in toluene at 50 °C resulted in higher yields, but slightly decreased molecular weights (entry 4). Changing the reducing agent from sodium to lithium or sodium–potassium alloy gave very low yields. The use of lithium metal often resulted in cyclo-oligomerization rather than linear polymerization and sodium–potassium alloy induced degradation of the polymers. Polygermanes with higher molecular weights can
be produced from dialkylgermanium dichlorides containing long-chain alkyl substituents. Poly(dihexyl)germane was prepared using the classical Wurtz-type reaction conditions and was isolated in 20% yield with a molecular weight of $M_w = 15.1 \times 10^3$ and a molecular weight distribution $M_w/M_n = 1.45$ (entry 6). Miller and Sooriyakumaran reported much higher molecular weights for poly(dihexyl)germane as prepared by the Wurtz-type coupling of $n$-Hex$_2$GeCl$_2$, but the isolated yields were very low (entry 8). The condensation of $n$-Hex$_2$GeBr$_2$ produced polymers with a narrow molecular weight distribution, but they were relatively low in molecular weight and had poor film-forming properties (entry 11). The use of diglyme as a co-solvent did not significantly increase the yields of polymers and resulted in considerably lower molecular weights.

Despite the fact that the use of sodium–potassium alloy in the Wurtz-type coupling results in chain scission of linear polygermanes, it was used for the reduction of trichlorogermanes to prepare branched polygermanes$^{33,34}$. The polygermynes (PhGe)$_n$ and ($n$-BuGe)$_n$ were isolated in 41% and 11% yield, respectively. When conventional Wurtz-type coupling conditions with sodium as reducing agent were applied to prepare (PhGe)$_n$, only poor yields (6.3%) were obtained and the polyphenylgermylene$^{35}$ had a molecular weight of only $M_w = 1.7 \times 10^3$. The reduction of $n$-BuGeCl$_3$ and $n$-HexGeCl$_3$ with sodium gave the corresponding polygermynes in yields of 39% to 50% and with molecular weights of $M_w = 3.8 \times 10^3$ ($M_w/M_n = 1.2$) and $4.3 \times 10^3$ ($M_w/M_n = 1.2$), respectively. Bulky organic groups in monoorganogermanium trichlorides reduce the tendency to give high molecular weight polymers upon reduction of the corresponding RGeCl$_3$ and favour the formation of cyclic and polycyclic oligogermanes. The X-ray crystal structure analyses of some polycyclic oligogermanes$^{36-41}$, such as the octagermacubane$^{236}$ and the hexagermaprismane$^{337}$, were reported. The latter compound was prepared by the reaction of bis(trimethylsilyl)methylgermanium trichloride with lithium in 12% yield, and compound 2 was isolated in 3% yield after reduction of 2,6-diethylphenylgermanium trichloride with Mg/MgBr$_2$.

The properties of poly($n$-butyl)germyne, ($n$-BuGe)$_n$$^{35}$, as prepared in THF at room temperature by employing SmI$_2$ as reducing agent, were reported to be similar to those of ($n$-BuGe)$_n$ prepared by Wurtz-type coupling, although slightly lower yields were obtained. The synthesis of a linear polygermane (Et$_2$Ge)$_n$ from Et$_2$GeCl$_2$ and SmI$_2$ as reducing
agent was also reported. The advantage of SmI₂ over sodium or sodium–potassium alloy is the application of mild reaction conditions. In addition, the use of sodium metal or sodium–potassium alloy is much more hazardous and requires special safety precautions but, on the other hand, its use is significantly cheaper than that of SmI₂.

ii. Ligand substitution polymerization. Another approach to polygermanes is the ‘ligand substitution polymerization’, which is based on the tendency of diorganogermynes to give high molecular weight polymers by Ge–Ge bond formation. The stable inorganic germynes GeX₂ (X = Cl, I) react with Grignard or organolithium reagents to give intermediates of the type R₂Ge, which immediately polymerise to give linear polygermanes (4) or cyclic oligogermanes (Scheme 2). Stabilization of the diorganogermynes can be achieved through the use of bulky substituents and/or intramolecular coordination and thus the polymerization process is inhibited.

\[

\text{Ge} \\
\text{R}
\end{array} \\
& n
\end{align*}
\]

(Scheme 2. Polymerization of diorganogermynes)

The reaction of n-BuLi with GeCl₂ in Et₂O at −78 °C gave a bimodal molecular weight distribution (Table 2, entry 3) similar to the polygermanes formed by Wurtz-type coupling reactions. The same reaction when carried out at higher temperatures or with n-BuMgBr under reflux conditions gave only a low molecular weight fraction (Table 2, entries 4–7). The reaction of GeCl₂ with PhLi gave only low molecular weight oligomers and the reaction of Gel₂ with PhMgBr gave mainly (Ph₃Ge)₂ and Ph₄Ge (31).

iii. Electrochemical synthesis. Given the more or less drastic reaction conditions of the Wurtz-type coupling which requires high-standard safety precautions, there is increasing interest in the electrochemical synthesis of polygermanes and polygermane–polysilane copolymers. Electrochemical reactions proceed under mild conditions and usually require only simple setups. The effects of the nature of the electrodes (sacrificial anode and cathode) and of the solvent on the electroreductive coupling of n-Hex₂GeCl₂ to give poly(dihexyl)germane were investigated. The selection of the cathode material was reported to be very important for the outcome of the reactions. It was shown that polygermanes with phenyl groups or short alkyl substituents such as methyl, ethyl or propyl gave relatively low yields, low current efficiencies and low molecular weights. In contrast, poly(dibutyl)-, poly(dipentyl)- and poly(dihexyl)germanes were synthesised in high yields, with high current efficiencies and with molecular weights in the range of \( M_w = 10 \times 10^3 \) to \( 15 \times 10^3 \). Based on experimental observations such as variable-temperature UV spectra, no difference between poly(dihexyl)germane obtained by electrolysis and the same polygermane obtained by Wurtz-type coupling reactions was observed. However, the yields for \((n\text{-Hex}_2\text{Ge})_n\) obtained by electrochemical reduction are twice as high as those obtained by the Wurtz-type method using a sodium dispersion in toluene as reducing agent (Table 2, entries 2 and 9). The electrochemical synthesis of a three-dimensional network polysilane–polygermane copolymer \([(\text{cyclo-HexSi})_x(\text{PhGe})_y] \) \( x/y = 1.04 \) (5) was also reported (Scheme 3, Table 2, entry 10).
22. Organometallic polymers of germanium, tin and lead 1549

\[
\begin{align*}
\text{Ph} & \quad \text{Ge} & \quad \text{Cl} \\
\text{Cl} & \quad \text{Si} & \quad \text{Cl} \\
\text{Cl} & \quad \text{Si} & \quad \text{Cl} \\
\text{Cu electrode} & \quad -6 \text{CuCl} \\
\end{align*}
\]

(5)

For comparison, the copolymerization starting from the same precursors, i.e. PhGeCl₃ and cyclo-HexSiCl₃, was performed under Wurtz-type conditions. The polymodal molecular weight distribution of the product thus obtained is broader as compared with the polymer prepared electrochemically. The optical spectra of a similar copolymer \([(n-\text{HexSi})_x(n-\text{HexGe})_y]_n\) were also reported. Linear polysilane–polygermane and polygermane–polygermane copolymers of the types \([(n-\text{Hex}_2\text{Ge})_x(n-\text{Hex}_2\text{Si})_y]_n\), \([(n-\text{Bu}_2\text{Ge})_x(n-\text{Hex}_2\text{Ge})_y]_n\) and \([(\text{MePh}_2\text{Ge})_x(n-\text{Pen}_2\text{Ge})_y]_n\) were prepared electrochemically from the corresponding diorganodichlorogermandanes and diorganodichlorosilanes. In case of the germane–germane copolymers, the monomer-to-monomer ratio in the resulting copolymer is strongly influenced by the monomer-to-monomer ratio in the solution at the beginning of the reaction. In contrast, the silane-to-germane ratio in \([(n-\text{Hex}_2\text{Ge})_x(n-\text{Hex}_2\text{Si})_y]_n\) was almost constant at 1/3 germane to 2/3 silane, regardless of the diorganodichlorogermandane-to-diorganodichlorosilane ratio in the electrolyte solution.

Molecular weights of the copolymers were obtained in the range of 1.0 \times 10^3 to 4.5 \times 10^3 and were shown to be lower than in the corresponding homopolymers. It was concluded that random copolymerization took place in each case. In order to obtain a block-like copolymer, \((n-\text{Bu}_2\text{Ge})_n\) was added to an electrolyte solution of diphenylgermanium dibromide. A copolymer \([(n-\text{Bu}_2\text{Ge})_{76}(\text{Ph}_2\text{Ge})_{24}]_n\) with a molecular weight of \(M_w = 1.4 \times 10^3, (M_w/M_n = 2.7)\) was obtained. Furthermore, this experiment shows that reductive cleavage of germanium–germanium bonds in the polymer chains is induced electrochemically.

The preparation of the structure-controlled silane–germane copolymer \((\text{Me}_2\text{SiPh}_2\text{GeMe}_2\text{Si})_n\) at low temperature using ultrasound was achieved (Scheme 4)⁵₈.

SCHEME 4. Electrochemical synthesis of a silane–germane copolymer with a \(-\text{Si}–\text{Ge}–\text{Si}–\) sequence

The copolymer \((\text{Me}_2\text{SiPh}_2\text{GeMe}_2\text{Si})_n\) (7) had a molecular weight of \(M_w = 1.1 \times 10^3, (M_w/M_n = 1.31)\) and was isolated in 25% yield. The authors claim that the polymerizability of \(\alpha,\omega\)-dichlorooligosilanes under electrochemical conditions is mainly affected by the substituents at the chlorinated terminal silicon atoms, which provides interesting options for the design of copolymers with ordered sequences of silicon and germanium atoms.

iv. Catalytic routes. In contrast to the synthesis of polysilanes⁵¹,⁶²,⁶³, the number of catalytic routes to polygermanes is limited⁶⁴–⁶⁶. The catalytic dehydrogenative coupling
of Ph$_2$GeH$_2$ with dimethyltitanocene as catalyst predominantly gave the linear tetramer Ph$_2$HGe(Ph$_2$Ge)$_2$GeHPh$_2$ instead of (Ph$_2$Ge)$_n$. Phenylgermane PhGeH$_3$ was reported to give a polymer under similar reaction conditions, but its structure was not sufficiently determined. The dehydrogenative coupling of phenylgermane by zirconocene-based catalysts gave high molecular weight polyphenylgermanes with a partially three-dimensional network structure (Scheme 5).

\[
\text{Cp}_2\text{ZrCl}_2 \text{ or Cp}^*\text{CpZrCl}_2 \quad 2n-\text{BuLi, 25 °C, toluene} \quad \rightarrow \quad [(\text{PhGeH})(\text{PhGe})_m]_n
\]

**SCHEME 5.** A catalytic route to polygermanes

The polymerization after one day of PhGeH$_3$ using Cp$_2$ZrCl$_2$ gave a polymer, which displayed a trimodal molecular weight distribution with $M_w (M_w/M_n) = 7.3 \times 10^4$ (3.7), $3.1 \times 10^3$ (1.3) and $6.3 \times 10^2$ (1.0) in a 62/32/6 ratio (Table 2, entry 11). The pentamethylcyclopentadienyl-substituted catalyst Cp$^*$CpZrCl$_2$ appeared to be less active in promoting chain growth than Cp$_2$ZrCl$_2$.

A very efficient catalytic process for the high-yield preparation of permethylated polygermanes starting from trimethylgermane was reported by Berry and coworkers (Scheme 6, Table 2, entries 12 and 13). In the catalytic cycle, element–element bonds are produced and methane is eliminated. The proposed mechanism for the formation of linear and branched polygermanes is shown in Schemes 7 and 8.

Since the catalyst Ru(PMe$_3$)$_4$(GeMe$_3$)$_2$ is synthesised from HGeMe$_3$ and Ru(PMe$_3$)$_4$Me$_2$, the latter can be used as a precatalyst. The polygermane is isolated as a colourless gum in 80–90% yield. The molecular weight of the product is almost independent of both the amount and the type of the catalyst used. However, it was demonstrated that the measured molecular weights differ significantly when different methods for their determination were employed. The common method of refractive index detection and calibration against polystyrene standards gave molecular weights in the range of $M_w = 2 \times 10^4$ to $M_w = 8 \times 10^4$. The values obtained by the SEC/viscometry method were up to three times higher.

**c. Properties. i. Chemical properties.** Polygermanes exhibit unique electronic and optical properties arising from $\sigma$-electron delocalization through the germanium–germanium bonds, including a red shift of $\lambda_{\text{max}}$ with increasing chain length, narrow emission bands and semiconducting behaviour. Potential applications of such polymers as photoconductors, photoresists, and non-linear optical materials were suggested. The polygermanes are usually obtained as colourless solids, which are soluble in solvents such as chloroform, hexane, toluene and THF. They are thermally stable, fairly resistant towards oxidation and hydrolysis. Poly(dihexyl)germane was found to be stable in toluene at 100 °C. Thermogravimetric analyses of poly(alkyl, phenyl)germanes and polygermynes revealed that weight loss starts at temperatures around 230 to 285 °C, and their residue weights decreased around 50% upon heating to 500 °C. Poly(dialkyl)germanes were reported to be stable up to temperatures higher than 300 °C. Polygermanes should be handled under exclusion of light. The germanium–germanium backbone in polygermanes is an intense ultraviolet (UV) chromophore and photodegradation of Ge–Ge bonds takes place. Therefore, the polygermanes are attractive materials for applications as UV photoresists. The photodegradation process in

SCHEME 7. Proposed mechanism for the demethanative coupling of HGeMe3 to give polygermanes.65

polygermanes was the topic of several recent reports. The analysis of photoproducts and laser flash photolysis of oligogermanes and high molecular weight polygermanes showed that in degassed cyclohexane solution both diorganogermylene extrusion and homolytic cleavage of the germanium–germanium bonds are competitive processes. The polygermyl radicals abstract a chlorine from polyhalomethanes to give the corresponding germanium chlorides and polyhalomethyl radicals. These radicals dimerise to give the corresponding polyhaloethanes. Furthermore, the polygermyl radicals add to 2,3-dimethyl-1,3-butadiene to give polyhalomethylchlorogermanes and add to 2,3-dimethyl-1,3-butadiene to give the corresponding germacyclopentene.

Poly(di-n-butyl)germane was decomposed to give low molecular weight oligomers after storage in THF for 2 h under exposure to daylight. Polygermane films, which have been deposited on quartz plates, are quite UV-light sensitive. Irradiation of the films with an 110-W low-pressure arc lamp (λ = 254 nm) for 1 min in air resulted in a tremendous decrease of the absorbance as a result of Ge–Ge bond cleavage. In the case of (MePhGe)$_n$ the molecular weight dropped from $M_w = 5.4 \times 10^3$ ($M_w/M_n = 1.4$) to $M_w = 2.9 \times 10^3$ ($M_w/M_n > 3.0$). The photodegradation process was also examined by X-ray photoelectron spectroscopy (XPS) and showed that the Ge–Ge bonds in films of polygermanes are almost quantitatively transformed into −Ge−O− sequences after 10 min of UV irradiation in air. Furthermore, laser flash photolysis was indicative for the formation of polygermyl radicals by homolytic Ge–Ge bond cleavage. In contrast to the results obtained for polygermanes in solution, no transient peaks assigned to diorganogermylenes in the absorption spectra were observed after laser flash photolysis. In conclusion, the key intermediates in the photodegradation of the polygermane films in air are polygermyl radicals generated by Ge–Ge bond cleavage. Polymers with −Ge−O−Ge−O− sequences in the backbone result from the oxygenation of polygermyl radicals.

### ii. Electronic properties

High molecular weight polygermanes show characteristic electronic absorption bands in the range of 300 to 360 nm (Table 3). The position of the absorption maxima depends on the nature of the substituents at germanium, the polymer phase, the molecular weight and the temperature. Furthermore, in polygermane–polysilane copolymers the Si-to-Ge ratio and the connectivity of germanium and silicon atoms in the polymer backbone also influence the electronic properties. Generally, the $\lambda_{max}$ values are shifted to higher wavelengths as the chain length of the alkyl groups increases. This trend may be explained by the difference in the chain conformation of linear polygermanes with larger alkyl substituents favouring a greater proportion of anti conformations over gauche conformations (Scheme 9).

Similarly, the replacement in polygermanes of alkyl substituents by phenyl groups results in significant red shifts of the absorption maxima (Table 3, entries 13–15). In contrast to several well-characterised poly(monoalkyl, monoaryl)germanes and poly(dialkyl)germane–poly(dialkyl)germane copolymers, reports on pure poly(diaryl)germanes were rare. The synthesis of poly(diphenyl)germane was reported, but as a result of its poor solubility in common organic solvents its characterization was insufficient.

Branched oligogermynes (RGe)$_n$ are yellow-coloured and exhibit an intense broad absorption from 200 nm tailing down into the visible region. The high extinction coefficients are attributed to an extension of the $\sigma$-conjugation effects in the branched germanium network.

In solution, the UV absorption characteristics of polygermanes may be different from those in the solid state. Poly(dihexyl)germane in solution has a $\lambda_{max}$ value of 327 nm, whereas the same polymer fraction deposited as a thin film on a quartz plate exhibits two
distinct $\lambda_{\text{max}}$ values at 317 and 339 nm$^{70}$ (entry 9). The $\lambda_{\text{max}}$ values of permethylated oligogermandes shift to higher wavelengths with increasing germanium chain length$^{25}$. It was suggested that the absorption maxima of polygermanes reach constant values as the number of germanium atoms becomes larger than approximately 20–30$^{31}$. In Table 3 some illustrative results for poly(dibutyl)germane are given (entries 3–6), which confirm this hypothesis. For \((n\text{-Bu}_2\text{Ge})_n\) the $\lambda_{\text{max}}$ value should be constant for molecular weights higher than approximately $5.8 \times 10^3$.

In solution, poly(dialkyl)germanes such as \((n\text{-Hex}_2\text{Ge})_n\), \((n\text{-Pen}_2\text{Ge})_n\) and \((n\text{-Bu}_2\text{Ge})_n\) show a distinct thermochromic behaviour$^{31,55}$. The $\lambda_{\text{max}}$ value of \((n\text{-Hex}_2\text{Ge})_n\) in pentane gradually shifts from $\lambda_{\text{max}} = 340$ nm at room temperature to $\lambda_{\text{max}} = 350$ nm at $-60$ °C.

\text{c}Polymer film.

\text{d}Not given.
The change in the absorption maximum is reversible. In contrast, (MePhGe)$_n$, (Et$_2$Ge)$_n$ and (n-HexPhGe)$_n$ do not show significant thermochromic properties with the $\Delta \lambda_{\text{max}}$ values being in the range of zero to five nanometer. The thermochromic effect in solution is suggested to be the result of conformational changes of the germanium chains with the proportion of anti conformation (Scheme 9) increasing as the temperature is decreased. A similar thermochromic behaviour was observed for polygermanes in the solid state. For example, a thin film of the polymer (n-Hex$_2$Ge)$_n$ showed a single broad absorption at 337 nm, which significantly decreased in intensity and which was finally replaced by a sharper absorption at 370 nm upon rapid cooling to $-12^\circ$C. Differential scanning calorimetry (DSC) measurements showed a strong endothermic effect at 12.4 °C and a strong exothermic effect at $-1^\circ$C attributed to a crystallisation process, which is in agreement with the reversible thermochromic effect. Poly(diocytgermane) shows a similar thermochromic behaviour, whereas for poly(dipentyl)germane the effect is less distinctive. The thermochromic effect in the solid state is suggested to be a result of side-chain crystallisation, which locks the polymer backbone in a regular anti conformation (Scheme 9). Polygermanes with long alkyl chains show the most distinct thermochromic effect.

Typically, polygermane–polysilane copolymers have similar UV properties as compared with polygermane and polysilane homopolymers. The thermochromic behaviour of the copolymers depends on their monomer-to-monomer ratios in the polymer chain and on the identity of the alkyl substituents. In principle, the fine tuning of the absorption maximum can be achieved by a controlled copolymerization. Unfortunately, the copolymers reported so far often have relatively low molecular weights, which in turn results in the $\lambda_{\text{max}}$ values being even lower than those observed for high molecular weight polysilanes (Table 4).

2. Polystannanes

a. Introduction. Polystannanes have more diffuse bonding orbitals than polysilanes and polygermanes; this is associated with a more distinct $\sigma$-conjugation. As a result, a higher metallic character, a lower band gap, a lower photochemical resistance and a more distinct thermochromic behaviour than that in polygermanes are to be expected. The electronic structure of polystannane (SnH$_2$)$_n$ was calculated by the first principal local density functional method and compared with that of polysilane (SiH$_2$)$_n$ and polygermane.
(GeH$_2$)$_n$. The calculated band gaps for (SnH$_2$)$_n$, (GeH$_2$)$_n$ and (SiH$_2$)$_n$ in anti conformation (Scheme 9) were reported to be 2.80, 3.31 and 3.89 eV, respectively$^{20}$. Recently, the use of polystannanes for the fabrication of electroluminescent devices and lasers$^{78,79}$, electroconductive films$^{80}$, colour filters for liquid crystal displays$^{80}$ and of materials with third-order optical non-linearity$^{81}$ were suggested. Further examples envisaged for applications are the use of polystannanes in photoresist technology, in microlithography, as semiconductors and as precursors to tin-based semiconducting materials$^{82}$.

A variety of synthetic methods for the Sn–Sn bond formation are available to date, the most common of which are (i) the coupling of organotin halides R$_n$SnX$_{4-n}$ with organostannylmetal compounds, R$_3$SnM (M = Li, Na, MgBr, MgCl), (ii) the reductive coupling of organotin halides, R$_n$SnX$_{4-n}$, by metals or electrochemically, (iii) the condensation reactions of organotin hydrides, R$_n$SnH$_{4-n}$, with compounds of the type R$_n$SnY$_{4-n}$ (e.g. Y = NR$_2$, OSnR$_3$, OR'), (iv) the insertion of stannylenes R$_2$Sn into tin–element bonds such as Sn–H, Sn–C, Sn–Sn and Sn–Cl and (v) the elimination of dihydrogen from organotin hydrides, R$_n$SnH$_{4-n}$, catalysed by amines or transition metal compounds. These general methodologies have been reviewed by Davies$^{83}$ and more recently by Braunstein and Morise$^{84}$, who focused on the ‘dehydrogenative coupling of hydrostannanes catalysed by transition-metal complexes’. Despite the wide range of synthetic methods for the formation of Sn–Sn bonds, the controlled preparation of high molecular weight polystannanes still remains a challenging target. The preparation of polysilanes is much more easily achieved, the reason being the higher stability of the Si–Si bond [E(Si–Si) = 340 KJ mol$^{-1}$] in comparison with the rather weak Sn–Sn bond [E(Sn–Sn) = 151 KJ mol$^{-1}$]$^{85}$.

In this section we give a comparative overview on the recent developments in the preparation of polystannanes and discuss their properties.

b. Syntheses. i. Oligostannanes via stepwise synthesis. Linear oligostannanes can be viewed as model compounds for linear polystannanes and different sequences of oligostannanes with varying chain lengths were prepared to elucidate the relationship of structure and electronic properties$^{16–19,21–24}$. Adams and Dräger reported the reaction of Ph$_3$SnLi with 1–(t-Bu$_2$Sn)$_n$–I ($n = 2–4$, 10) to give mixtures of the linear oligostannanes Ph$_3$Sn(t-Bu$_2$Sn)$_n$SnPh$_3$ ($n = 1–4$, 11) depending on the reaction conditions employed (Scheme 10)$^{18}$. This experiment demonstrated the lability of the Sn–Sn bond and the tendency of oligo- and polystannanes to undergo equilibration processes in solution to give the thermodynamically most stable compounds.

$$\begin{align*}
2 \text{Ph}_3\text{SnLi} + 1–(\text{t-Bu}_2\text{Sn})_n–\text{I} \rightarrow & \text{Ph}_3\text{Sn}(\text{t-Bu}_2\text{Sn})_n\text{SnPh}_3 \\
& \text{n = 2–4, 10} \\
& \text{2 LiI} \rightarrow \text{n = 1–4, 11}
\end{align*}$$

SCHEME 10. Synthesis of oligostannanes via metal–halogen exchange

A stepwise construction of oligostannanes containing six tin atoms in the backbone is based on the tin–tin bond-forming hydrostannolysis reaction$^{86}$. To produce higher-order oligostannanes, the $\beta$-alkoxy substituent –CH$_2$CH$_2$OEt was used as protecting group at tin, which can easily be transformed into a Sn–H functionality by reaction with DIBAL-H ($i$-Bu$_2$AlH). The Sn–H bond serves as the site for extended chain growth of the polystannane skeleton$^{19}$ (Scheme 11). This approach is very tedious and oligostannanes (12) with up to a maximum of only six tin atoms in the backbone were prepared.

SCHEME 11. Synthesis of oligostannanes

The development of this synthetic methodology has led to the preparation of oligostannanes with up to fifteen tin atoms in the linear chain

\((\text{Scheme 12})\) This was achieved by reaction of dibutyl(2-ethoxyethyl)stannane \((\text{13})\) with 0.2–0.3 equiv of lithium diisopropylamide (LDA) in THF to presumably generate an intermediate family of hydride-terminated oligostannanes \((\text{14})\), which were then reacted with dibutyl(dimethylamino)(2-ethoxyethyl)stannane \((\text{13})\) to give the final product \((\text{15})\). The formation of stannylenes, which insert into an Sn–H bond was proposed to explain the chain growth mechanism. However, small amounts of the cyclic oligomers \((\text{87})\) \(\text{cyclo-}(n$-$Bu$_2$Sn)$_5$\) and \(\text{cyclo-}(n$-$Bu$_2$Sn)$_6$\) were also formed and the short-chain oligomers predominate over oligomers with chain lengths of \(n > 10\).

SCHEME 12. Synthetic strategy to prepare oligostannanes with up to 15 tin atoms in the linear chain

Several cyclic and polycyclic oligostannanes with a rich structural diversity have been reported in the literature and it was concluded by Sita that the concepts and strategies established in organic chemistry can successfully be applied for the construction of polystannane frameworks as well. The polycyclic oligostannanes \((\text{16}–\text{19})\) are representative examples for this class of compounds.
\[ R = 2,6-\text{Et}_2\text{C}_6\text{H}_3 \]

**ii. Polystannanes via Wurtz-type coupling.** Early attempts to prepare high molecular weight polystannanes were directed towards the Wurtz-type coupling of diorganotin dichlorides\textsuperscript{86,88} because this method was known to be successful for the preparation of polysilanes\textsuperscript{13}. However, initially this method failed and only low molecular weight oligomers\textsuperscript{86} were formed. Nevertheless, in 1992 the first high molecular weight organotin polymer \( \text{H}(n\text{-Bu}_2\text{Sn})_n\text{H} \) (20) was reported, which was prepared by the Wurtz-type coupling of \( n\text{-Bu}_2\text{SnCl}_2 \) using sodium dispersion in toluene and the catalytic effect of 15-crown-5 ether (Table 5, Scheme 13)\textsuperscript{89}. However, following the above-mentioned experimental procedure for the preparation of 20\textsuperscript{89}, Tilley and coworkers\textsuperscript{82,90} failed to reproduce the results. The \(^{119}\text{Sn}\) NMR spectrum of the crude reaction mixture was consistent with the formation of small amounts of \( \text{H}(n\text{-Bu}_2\text{Sn})_n\text{H} \), but the major signals were assigned to the cyclic oligomers \( \text{cyclo}(n\text{-Bu}_2\text{Sn})_5 \) and \( \text{cyclo}(n\text{-Bu}_2\text{Sn})_6 \). A more detailed analysis of the reaction conditions used for the Wurtz-type coupling of \( n\text{-Bu}_2\text{SnCl}_2 \) in toluene at 60°C using a sodium dispersion and catalytic amounts of 15-crown-5 ether revealed a strong dependence of the polymer-to-oligomer ratio on the reaction conditions employed\textsuperscript{91}. During the first 2 h of the reaction, very little polymer is formed and most of the product is composed of low molecular weight cyclic oligomers. The maximum yield of high molecular weight polystannane (\( M_w \approx 7.7 \times 10^5 \)) was obtained after a reaction time of approximately 4 h. Prolonged reaction rapidly lead to chain scission and after 5.5 h the majority of polymer was reconverted into cyclic oligomers. The use of ultrasound had no influence on the degree of polymerization, but the time required to reach the optimal conditions was approximately halved.

To circumvent the problem of polystannane degradation by sodium-induced Sn\textendash{}Sn bond cleavage, a new synthetic procedure for the preparation of polystannanes under
### TABLE 5. Representative examples for the preparation of poly(dialkyl)stannanes by Wurtz-type coupling A, SmI$_2$-induced reduction B, electrochemical reduction C and dehydrogenative coupling D

Mild conditions using SmI$_2$ or alkali earth metal (Mg, Ca) vapor-solvent co-condensates was investigated$^{42,92}$. The resulting polystannanes (R$_2$Sn)$_n$ (R = Me, Et, n-Hex) showed narrow molecular weight distributions ($M_w/M_n = 1.2–1.5$), but only moderate molecular weights ($M_w = 1.1–4.8 \times 10^3$) were observed.

Using the Wurtz-type coupling reaction, Jones and coworkers reported the synthesis of a high molecular weight organostannane–organosilane copolymer (21)$^{93}$ starting from MePhSiCl$_2$ and $n$-Bu$_2$SnCl$_2$ in a 4 : 1 molar ratio (Scheme 14). The reaction was carried out with sodium metal, and MePhSiCl$_2$ was used as both reagent and solvent. After the work-up procedure, a product was obtained for which a Si : Sn ratio of 6.2 : 1 was estimated on the basis of the $^1$H NMR spectrum. The copolymer was isolated in 11% yield and had a molecular weight of $M_w = 15.1 \times 10^3$ and a molecular weight distribution of $M_w/M_n = 2.3$. The same reaction and work-up procedure was carried out using toluene,
resulting in the formation of a copolymer with a lower molecular weight \( (M_w = 3 \times 10^3, M_w/M_n = 1.5) \).

\[
n\text{Bu}_2\text{SnCl}_2 + \text{PhMeSiCl}_2 \xrightarrow{\text{Na, 120 °C}} \left[ \begin{array}{c} \text{Bu}^n \\ \text{Sn} \\ \text{Bu}^n \end{array} \right] + \left[ \begin{array}{c} \text{Ph} \\ \text{Si} \\ \text{Me} \end{array} \right]_m
\]

(21)

Matyjaszewski and coworkers\(^9^4\) reported the Wurtz-type synthesis of organostannane–organosilane copolymers under the influence of ultrasound starting from PhMeSiCl\(_2\) and Ph\(_2\)SnCl\(_2\). This approach resulted in the formation of low molecular weight copolymers with a broad molecular weight distribution \( (M_w = 4 \times 10^3, M_w/M_n = 3.7) \). The \(^1\)H NMR spectrum was indicative for a Si : Sn ratio of 1.4 : 1\(^9^4\).

iii. Polystannanes via electrochemical synthesis. Electrochemical reduction of diorganotin dihalides is expected to be the most important approach for the large-scale preparation of polystannanes\(^2^2\). However, so far only \((n-\text{Bu}_2\text{Sn})_n\) and \((n-\text{Oct}_2\text{Sn})_n\) were prepared by electrochemical synthesis\(^9^5\) (Table 5, Scheme 15). The reactions were carried out in 1,2-dimethoxyethane (DME) as solvent and with tetrabutylammonium perchlorate as supporting electrolyte. The yields reported were 40–60% for \((n-\text{Bu}_2\text{Sn})_n\) and 30–50% for \((n-\text{Oct}_2\text{Sn})_n\). The polystannane \((n-\text{Bu}_2\text{Sn})_n\) showed molecular weight distributions in the range of \( M_w/M_n = 2.1–2.6 \) and molecular weights of approximately \( M_w = 1.1 \times 10^4 \). The use of THF as solvent gave a narrower molecular weight distribution of \( M_w/M_n = 1.3 \), but also lower molecular weights of \( M_w = 0.64 \times 10^4 \), which is attributed to a polystannane degradation resulting from residual moisture in the THF solutions. For \((n-\text{Oct}_2\text{Sn})_n\) a molecular weight of \( M_w = 0.59 \times 10^4 (M_w/M_n = 1.7) \) was reported.

\[
n\text{Bu}_2\text{SnCl}_2 + 2\text{ne}^- \xrightarrow{-2n \text{Cl}^-} \left[ \begin{array}{c} \text{R} \\ \text{Sn} \\ \text{R} \end{array} \right]_n
\]

R = n-\text{Bu}, n-\text{Oct} (22)

SCHEME 15. Electrochemical synthesis of polystannanes

Electrochemical syntheses were used to prepare organostannane–organosilane and organostannane–organogermane copolymers\(^9^6\). Poly(dibutylstannylene-co-dibutylsilylene) and poly(dibutylstannylene-co-dibutylgermylene) were synthesised by the reduction of mixtures of dibutyl dichlorostannane and dibutyl dichlorosilane and dibutyl dichlorogermane, respectively, using tetrabutylammonium perchlorate as the supporting electrolyte and DME as solvent. The copolymers were isolated in low yields, had relatively high molecular weights but broad molecular weight distributions. For example, a copolymer \((n-\text{Bu}_2\text{Sn})_{0.47}(n-\text{Bu}_2\text{Si})_{0.57}\) was isolated in 11% yield from a reaction mixture containing
Organometallic polymers of germanium, tin and lead  

$n$-Bu$_2$SnCl$_2$ and $n$-Bu$_2$SiCl$_2$ in a one-to-one ratio. The copolymer had a molecular weight of $M_w = 1.26 \times 10^5$ and a molecular weight distribution of $M_w/M_n = 13$.

iv. Polystannanes via catalytic routes. The transition metal complex-catalysed dehydrogenative coupling of secondary stannanes R$_2$SnH$_2$ is a promising approach to high molecular weight polystannanes. The use of a variety of catalysts based on Ti, Zr, Hf, Sm, Rh, Cr, Mo, W and heterobimetallic Fe–Pd complexes was reported. The compounds 23–25 represent three examples of catalysts used for the dehydrogenative coupling of organostannanes.

The dehydropolymerization of $n$-Bu$_2$SnH$_2$ as catalysed by heterobimetallic Fe–Pd complexes gave mixtures of cyclic and linear polystannanes with the latter having a broad molecular weight distribution. On the basis of the relationship between the $\lambda_{max}$ value and the chain length for (R$_2$Sn)$_n$, the formation of high molecular weight polymers was suggested, but no molecular weight determination was reported. In case of the dehydropolymerization of Ph$_2$SnH$_2$ only the cyclic pentamer, cyclo-(Ph$_2$Sn)$_5$, and hexamer, cyclo-(Ph$_2$Sn)$_6$, were formed.

Metallocene-based catalysts were successfully used for the dehydropolymerization of secondary stannanes R$_2$SnH$_2$ (Table 5, Scheme 16). The syntheses of high molecular weight poly(dialkyl)stannanes (26) and poly(diarylstannanes (27) using different Cp$_2$ZrR$_2$ derivatives as catalysts were reported. The most active catalyst reported so far for the synthesis of high molecular weight poly(dibutyl)stannanes is Me$_2$C($\eta^5$-C$_5$H$_4$)$_2$Zr[Si(SiMe$_3$)$_3$]Me (24). It was claimed to produce H($n$-Bu$_2$Sn)$_n$H (26) with a molecular weight up to $M_w = 6.69 \times 10^4$ and a molecular weight distribution of $M_w/M_n = 3.30$. However, the polystannane was contaminated by ca 18% (by weight) of low molecular weight cyclic oligomers (28) with the cyclic pentamer cyclo-($n$-Bu$_2$Sn)$_5$ predominating. Usually, the polymerizations are initiated by addition under nitrogen of the neat monomer to the catalyst (2 mol%). The addition of small amounts of solvent (1 molar amount of toluene per monomer) significantly increased the molecular weights of the resulting polymers, but substantial dilution of the monomer predominantly lead to cyclization.

\[
\begin{align*}
R_2SnH_2 & \xrightarrow{[cat]} H \longrightarrow (R_2Sn)_n \longrightarrow H + cyclo-(R_2Sn)_n \\
(26) & \text{R = alkyl} \\
(27) & \text{R = aryl}
\end{align*}
\]

SCHEME 16. Catalytic dehydrogenative coupling of diorganotin dihydrides

Polymers with the highest molecular weights were obtained for secondary stannanes with long alkyl chains, e.g. a molecular weight of $M_w = 1.49 \times 10^5$ ($M_w/M_n = 8.76$) was observed for H($n$-Oct$_2$Sn)$_n$H$^{82}$. 

In case of the diorganostannanes Me₂SnH₂, PhMeSnH₂ and Ph₂SnH₂ only low molecular weight oligomers could be obtained, which is attributed to the low solubility of the corresponding oligostannanes. In order to circumvent this problem, monomeric diarylstannanes Ar₂SnH₂ with the solubilizing substituents \( \text{Ar} = p\text{-t-BuC₆H₄}, \ p\text{-n-HexC₆H₄}, \ o\text{-EtC₆H₄}, \ p\text{-n-BuOC₆H₄}, \ o\text{-Et}, p\text{-t-BuC₆H₃} \) and \( p\text-\text{(Me₃Si)₂NC₆H₄} \) were used in the \( \text{Cp₂ZrMe₂} \)-catalysed dehydropolymerization. At monomer concentrations in pentane above 0.09 M, relatively high molecular weight polymers \( \left[H(p\text{-t-BuC₆H₄})₂Sn\right]_nH \) were obtained (\( M_w = 5.4 \times 10^4; M_w/M_n = 3.6 \) for the linear fraction), whereas at low monomer concentrations (0.01–0.03 M) only low molecular weight oligomers were formed. The use of donor solvents such as pyridine inhibited the polymerization. A relatively narrow molecular weight distribution of \( M_w/M_n = 1.5 \) was observed when the dehydropolymerization of diaryltin dihydrides was carried out in the melt, but only moderate molecular weights \( M_w = 0.15 \times 10^4 \) were obtained together with a large fraction of cyclic oligomers. Notably, the dehydrogenative coupling of \( (p\text{-t-BuC₆H₄})₂SnH₂ \) predominantly gave the cyclic hexamer as by-product, whereas the cyclic pentamer was the major by-product in the polymerization of dialkylstannanes.

Hafnocenes are less active polymerization catalysts and metalocene chlorides are almost inactive. However, treatment of \( \text{[Cp₂MCl₂]} (\text{M} = \text{Zr}, \text{Hf}) \) with \( n\text{-BuLi} \) provided efficient catalysts for the dehydropolymerization of \( n\text{-Bu₂SnH₂} \). Mixtures of oligostannanes and cross-linked insoluble polystannanes were reported to be formed upon treatment of \( n\text{-Bu₂SnH₂} \) with \( \text{[Cp₂MCl₂]/Red-Al} (\text{M} = \text{Ti}, \text{Zr}, \text{Hf}) \) and \( \text{[M(CO)₆]/Red-Al} (\text{M} = \text{Cr}, \text{Mo}, \text{Wo}) \) as combination catalysts. The same catalysts were used in the dehydrogenative coupling of \( n\text{-Bu₃SnH} \) for which cross-linked polystannanes were observed as minor products. In both cases, the formation of cross-linked polystannanes is suggested to result from a combination of disproportionation and dehydrocoupling. The same combined processes were observed for the \( \text{[HRh(CO)(PPh₃)₂]-catalysed dehydropolymerization of n-Bu₂SnH₂} \). Interestingly, rapid addition of the catalyst to neat \( n\text{-Bu₂SnH₂} \) gave the cyclic pentamer and hexamer, whereas slow addition of the rhodium catalyst to a dilute solution of the monomer in toluene produced a highly branched, high molecular weight polystannane with a narrow molecular weight distribution (\( M_w = 5.02 \times 10^3; M_w/M_n = 1.43 \)).

Research on the optimization of reaction conditions and the elucidation of reaction mechanisms for the dehydrogenative polymerization of secondary stannanes is rather limited. In this context, Tilley and coworkers proposed a chain-grow mechanism (Scheme 17), which is similar to that proposed for the dehydropolymerization of organosilanes.

c. Properties. i. Chemical properties. The polystannanes reported to date are described as yellow- or orange-coloured viscous oils or solids. They are thermally stable at room temperature, but sensitive towards moisture and light. In air, solid samples decompose very slowly and poly(diaryl)stannanes are air-stable over at least several weeks in the dark. No decomposition of \( \text{H(n-Bu₂Sn)}_nH \) in pentane took place, even when oxygen was bubbled through its solution. It was concluded that polystannanes are stable towards oxygen but extremely reactive to moisture. In solution, poly(diaryl)stannanes as well as poly(dialky)stannanes photochemically degrade to give cyclic oligomers, predominantly the pentamer and the hexamer. Exposure of \( \text{H(p-t-BuC₆H₄)}_₂Sn\text{H}_n \) in THF to light for 30 min resulted in complete degradation to give a mixture of cyclic oligomers. Therefore, polystannanes should be handled under anaerobic conditions and exclusion of light. Only a few silane–stannane and germane–stannane copolymers were reported and their properties remain mainly unexplored. Okano and Watanabe
22. Organometallic polymers of germanium, tin and lead

\[

H & \longrightarrow (R_2Sn)_m(R_2Sn)_n \longrightarrow H
\end{align*}
\]

**SCHEME 17.** Proposed mechanism for the transition metal catalysed dehydropolymerization of organostannanes

demonstrated that an increase of the \(n\)-Bu\(_2\)Si content in polystannane–polysilane copolymers \([(n\mbox{-}Bu_2Si)_m(n\mbox{-}Bu_2Sn)_n]\) results in a substantial lower tendency for decomposition of the copolymers, but also results in absorption peaks at shorter wavelengths compared with that of \((n\mbox{-}Bu_2Sn)_n\) at \(\lambda_{\text{max}} = 380\) nm. The same tendency was observed in the corresponding poly(dibutyl)stannane–poly(dibutyl)germane copolymers, but in addition the absorption peak of a copolymer with a Sn : Ge ratio of 32 : 68 was observed at \(\lambda_{\text{max}} = 315\) nm, which is at an even shorter wavelength than that of poly(dibutyl)germane itself (\(\lambda_{\text{max}} = 324\) nm)\(^{96}\).

Thermogravimetric analyses (TGA) of poly(dialkyl)stannanes under nitrogen showed onset temperatures for thermal decomposition in the temperature range of 250–280°C, which is close to the values for related polydialkysilanes\(^ {82}\). The TGA analyses of poly(diaryl)stannanes\(^ {100}\) show onset temperatures for the decomposition in the range of 203–327°C. Thermal decomposition of polystannanes leads to tin and tin oxide, and thus application of these materials for the preparation of conductors or coatings in semiconductors may be envisaged. It is worth noting that electronic conductivities of about 0.01–0.3 S cm\(^{-1}\) were observed for thin films of the polystannanes after exposure to SbF\(_5\) vapor as an oxidant\(^ {82}\).

Polystannanes are routinely characterised by gel permeation chromatography (GPC, polystyrene standard), UV spectroscopy, thermal gravimetric analysis (TGA) and \(^1\text{H}\) and \(^{119}\text{Sn}\) NMR spectroscopy. Especially, \(^{119}\text{Sn}\) NMR in solution is a powerful tool to determine the ratio of high molecular weight polymers to cyclic oligomers. The signals assigned to the cyclic oligomers are usually low-frequency shifted compared with the signals of the corresponding polystannane. Thus, the hexamer cyclo-\([(p-t\mbox{-}BuC_6H_4)_2Sn]_6\) has a \(^{119}\text{Sn}\) NMR chemical shift \(\delta = 221\), which is quite different from the chemical shift \(\delta = 197\) of the linear polymer \(H[(p-t\mbox{-}BuC_6H_4)_2Sn]_nH\). \(^{119}\text{Sn}\) NMR chemical shifts of some representative polystannanes and cyclic oligomers are given in Table 6. \(^1\text{H}\) NMR spectroscopy was used to determine the ratio of cyclic oligomers to linear polymers in the case of the polymerization of \(n\mbox{-}Bu_2\text{SnH}_2\) and \(n\mbox{-}Hex_2\text{SnH}_2\). The terminal methyl groups give rise to distinct triplets which are well separated for the linear and the cyclic compounds. For poly(diocetyl)stannane and the related cyclic diocetylstannanes, however, the \(^1\text{H}\) NMR spectra are very similar and consequently, these compounds could not be distinguished by this method\(^ {82}\).

\textit{ii. Electronic properties.} The UV-visible spectroscopic properties of oligostannanes\textsuperscript{18,19,22,30}, polystannanes\textsuperscript{42,82,90–92,95,97,98,100} and organosilane–organostannane copolymers\textsuperscript{93,96} have attracted great interest. Concerning the electronic spectra of oligostannanes, homologous series of linear oligostannanes show red-shifting of the lowest energy transition with increasing chain length reaching a plateau value. The specific positions and magnitudes of these transitions are strongly influenced by the nature of the substituents at tin.

All soluble high molecular weight polystannane derivatives absorb strongly in the UV. In Table 7, the $\lambda_{\text{max}}$ values of some representative homopolymers are given. Extinction coefficients $\varepsilon_{\text{max}}$ in the range of $4.2 \times 10^3$ to $6.3 \times 10^4$ were reported\textsuperscript{82}. At room temperature, high molecular weight poly(dialkyl)stannanes exhibit $\lambda_{\text{max}}$ values in the range of 380–400 nm. The actual value observed may vary depending upon the percentage of cyclic oligomers present, the temperature and the polymer phase (e.g. solid vs solution). For comparison, the $\lambda_{\text{max}}$ values for Et(SnEt$_2$)$_6$Et (Sn$_6$)$_3$\textsuperscript{30}, [EtO(CH$_2$)$_2$-$\text{n-Bu}_2\text{Sn}$]$_2$Sn(Bu-t)$_2$ (Sn$_9$)$_2$\textsuperscript{23} and [EtO(CH$_2$)$_2$-$\text{n-Bu}_2\text{Sn}$($\text{n-Bu}_2\text{Sn}$)$_6$]$_2$Sn(Bu-n)$_2$ (Sn$_{15}$)$_2$\textsuperscript{22}.

\textsuperscript{a}Molecular weight measured by GPC. $M_w$ is weight-average molecular mass.

\textsuperscript{b}Molecular weight distribution. $M_n$ is number-average molecular mass.

\textsuperscript{c}Not given.
are 325 nm, 342 nm and 362 nm, respectively. A sample of H\(\text{Bu}_2\text{Sn})_n\text{H} (M_w = 4.12 \times 10^4, M_w/M_n = 2.96)\) displayed a transition at 390 nm in pentane, whereas the corresponding polysilane \(\text{Bu}_2\text{Si})_n\text{H}\) and polygermane \(\text{Bu}_2\text{Ge})_n\) have limiting \(\lambda_{\text{max}}\) values of 314 and 333 nm, respectively. Thus, the \(\sigma \rightarrow \sigma^*\) transitions for polystannanes are red-shifted by ca 70 nm with respect to comparable polysilanes and by ca 50 nm with respect to comparable polygermanes.

Polystannanes exhibit \(\lambda_{\text{max}}\) values attributed to the \(\sigma \rightarrow \sigma^*\) transitions in the range of 430–506 nm. A significant \(\sigma \rightarrow \pi\) interaction was suggested to occur in these polymers, which lowers the band gaps with respect to those for related poly(dialkyl)-stannanes. A sample of H\(\text{Et}_{\text{p}}\text{Bu}_2\text{Sn})_n\text{H}\) with a molecular weight of \(M_w < 5 \times 10^3\) exhibited a band gap of ca 2.3 eV, the smallest band gap reported for \(\sigma\)-conjugated linear polymers so far. There is an approximately linear correlation for the poly(diaryl)stannanes between the polymer band gap (as indicated by the \(\lambda_{\text{max}}\) values) and the \(\text{Sn}^\text{119}\) NMR chemical shifts, with the \(\text{Sn}^\text{119}\) NMR resonances shifting to higher frequencies as the band gap is narrowed.

The hyperbranched polymer, as obtained by the dehydropolymerization of \(\text{Bu}_2\text{SnH}_2\) with a rhodium catalyst, has a \(\lambda_{\text{max}}\) value of 394 nm, which is slightly red-shifted with respect to high molecular weight poly(dibutyl)stannane (Table 7, entries 2–5).

Poly(diocetyl)stannane and poly(dihexyl)stannane exhibit a reversible thermochromic behaviour as a result of a phase transition at ca 40 °C. A discolouration of the polymers was observed upon slightly warming above room temperature and variable-temperature UV-vis spectrometry showed a reduction of the \(\lambda_{\text{max}}\) values of \((\text{Oct}_2\text{Sn})_n\) in toluene solution from 384 to 369 nm and of \((\text{Hex}_2\text{Sn})_n\) from 398 to 382 nm. On the other hand, however, poly(dibutyl)stannane and poly(diaryl)stannane do not exhibit thermochromic behaviour in the temperature range between −10 to 90 °C and −20 to 90 °C, respectively.

**B. Polymers Containing Germanium in the Backbone**

**i. Germanium containing \(\sigma\text{-}\pi\)-conjugated linear chain polymers.** Polygermanes show interesting physical properties as a result of the \(\sigma\)-conjugation in the germanium backbone, whereas unsaturated organic polymers exhibit conductivity as a result of \(\pi\)-conjugation in the linear carbon chain. The combination of \(\sigma\) and \(\pi\)-conjugated structure fragments was expected to give access to a new class of polymers. A theoretical investigation on silicon- and germanium-containing linear chain polymers of the type \(29^{106}\) showed that the electronic properties of the germanium-containing polymers are close to those of the silicon-containing analogues.

\[
\left[ \text{MR}_2 \underset{n}{\cdots} \text{MR}_2 \underset{n}{\cdots} \text{Z} \right]
\]

(29)

\(\text{M} = \text{Ge, Si} \)
\(\text{R} = \text{H, Me, F} \)
\(\text{Z} = \text{CH=CH} \cdots, \text{C} \equiv \text{C} \cdots, \)

The calculated band gaps for \([\text{GeH}_2\text{GeH}_2\text{CH=CH}]_n\), \([\text{GeMe}_2\text{GeMe}_2\text{CH=CH}]_n\) and \([\text{GeF}_2\text{GeF}_2\text{CH=CH}]_n\) were estimated to amount to 3.22 eV, 3.06 eV and 2.93 eV,
respectively. For comparison, the calculated band gap for \[(\text{SiH}_2)_2\text{CH}═\text{CH}\] \(n\) was reported to be 3.07 eV. In polymers of the general formula \([\text{MR}_2-\text{MR}'_2-Z]_n\) (\(E = \text{Ge}, \text{Si}; R, R' = \text{H}, \text{CH}_3, p-\text{Tol}, \text{F}; Z = -\text{CH}═\text{CH}, -\text{C}≡\text{C}, -2,5-\text{C}_4\text{H}_2\text{S}\)) the highest-energy occupied band corresponds to a delocalised \(\sigma\) interaction along the polymer skeleton and the lowest-energy unoccupied band is related to a \(\text{C}−\text{C} \pi^*\) antibonding interaction. Some thiophene-based polymers with germanium in the backbone were prepared in order to study possible \(\sigma\)-\(\pi\)-conjugation along the polymer skeleton\(^{107−110}\). Compounds 30 and 31 represent two examples, in which alternating dialkylgermanium moieties and thiophene units build up the polymer skeleton\(^{109,110}\).

SCHEME 18. Wurtz-type coupling of bis(halodiorganogermanium) derivatives

In a similar manner, digermanylene polymers 34 were prepared by the treatment of di-Grignard reagents with 1,2-dichlorotetramethyldigermane (Scheme 19)\(^{107}\). The molecular weights (\(M_w = 2.6\) to \(4.7 \times 10^3\)) of the polymers 34 were significantly lower compared with those of the digermanylene polymers 33\(^{108}\).

The molecular weights of the digermanylene polymers do not significantly influence the absorption properties of the polymers. The absorption spectra show \(\lambda_{\text{max}}\) values in the range of 244–260 nm depending on the \(\pi\)-electron system bridging the organogermanium moieties. These values are relatively low compared with \(\lambda_{\text{max}}\) values of 300–335 nm reported for polygermanes. In general, polymers composed of alternating digermanylene units and \(\pi\)-electron systems are insulators. Upon doping with an electron acceptor, the polymers can be switched from their neutral insulating state to a doped conducting state. For instance, upon doping with \(\text{SbF}_5\) or \(\text{I}_2\), the digermanylene polymers 33 and 34 show conductivities in the range of \(10^{-4} \, \text{S cm}^{-1}\). The polymers are light-sensitive,
which was demonstrated by the decrease in the intensity of the absorbance of a thin \([-\text{GeMe}_2-1,4-\text{C}_6\text{H}_4-\text{GeMe}_2-]\)_n film upon irradiation (\(\lambda = 254\ \text{nm}\)) at room temperature in air\(^{107}\). The decrease in the absorbance intensity was attributed to Ge–Ge bond cleavage and the formation of Ge–O–Ge fragments.

Poly[(germylene)diacetylenes] contain alternating \(-\text{GeR}_2-\) and diyne units in the polymer backbone. The reactions of dilithiobutadiyne or the corresponding di-Grignard reagent with diorganogermanium dibromides gave \([-\text{GeRR'}\equiv\text{C}≡\text{C}≡\text{C}]-\)_n (\(R, R' = \text{Me, Et, Ph}\) \(^{35}\)) in isolated yields of 50–87\% (Scheme 20).

The polymers \(^{35}\) are cream-coloured solids, which are soluble in common organic solvents. In contrast to pure organic polynes, the poly[(germylene) diacetylenes] \(^{35}\) are quite stable at higher temperatures. Thermally induced degradation reactions were observed only at temperatures above 150°\(C\). Weight-average molecular weights in the range of \(M_w = 2.3–3.1 \times 10^3\) were determined by gel permeation chromatography (GPC). These relatively low molecular weights correspond to degrees of polymerization in the range of \(n_w = 8–15\), depending on the substituents at germanium. The poly[(germylene)diacetylenes] \(^{35}\) were reported to be insulators, with conductivities in the range of \(10^{-12}–10^{-15}\ \text{S cm}^{-1}\). Upon doping with FeCl\(_3\) the conductivities increased to \(10^{-4}–10^{-5}\ \text{S cm}^{-1}\), which is comparable with conductivity values of conjugated organic polymers.

The pyrolysis of poly[(germylene)diacetylenes] \(^{35}\) under argon was studied\(^{112}\). At relatively low temperatures (150–250°\(C\)) cross polymerization through the triple bonds was observed and further heating to temperatures up to 1200°\(C\) provided crystalline
germanium clusters, together with a large amount of free carbon (40–61%). When the poly[(germylene)diacetylenes] were pyrolysed under an atmosphere of ammonia at 750 °C, germanium nitride, Ge₃N₄, and metallic germanium were formed. Another type of conjugated polymers, in which germole rings are incorporated into the polymer backbone, was recently reported by Tilley and coworkers. They prepared bis-p-halophenyl-2,5-germole monomers, which were polymerised via nickel-catalysed coupling to give oligo- and poly-2,5-diphenylgermoles of type (Scheme 21). The high molecular weight polymer (Mₘ = 2 × 10⁴) shows an absorption at λ_max of 442 nm, which is red-shifted with respect to that of (λ_max = 376 nm) and poly(diphenyl-1,4-cis-dienylene) (λ_max = 396 nm). It was suggested that the increased λ_max value of compared with the latter organic polymer results either from a decrease in the steric interactions along the polymer chain allowing better orbital overlap, or from a lowering of the LUMO level in the π-system by incorporation of the germole ring. Compound shows photoemission properties, suggesting potential applications in light-emitting devices.

ii. Polyferrocenylgermanes. Thermal ring-opening polymerization (ROP) was used to prepare high molecular weight poly(ferrocenyl)germanes (Scheme 22). This new class of polymers shows thermal stabilities, morphologies and electrochemical properties similar to those of poly(ferrocenyl)silanes, which have been reported earlier. In the thermal ROP process, the germanium bridged [1]ferrocenophanes are simply heated under vacuum to induce the polymerization. In comparison with ferrocene, the cyclopentadienyl rings in [1]dialkylgermaferrocenophanes are tilted against each other. The release of the steric strain by the polymerization process was reported to be the driving force to give linear polymers of the type [Fe(η⁵-C₅H₃R')₂GeR₂]ₙ (R' = H, SiMe₃). The temperature required for the polymerization largely depends on the substituent pattern at germanium and the organic substituents R at the cyclopentadienyl ring, e.g. Fe(η⁵-C₅H₄)₂GeMe₂ polymerises at 90 °C and Fe(η⁵-C₅H₄)₂GePh₂ at 230 °C. The molecular weights of polyferrocenylgermanes as determined by gel permeation chromatography (GPC) are usually in the range of 5.0 × 10⁴–2.0 × 10⁶ with varying polydispersities. It is noteworthy that GPC seems to underestimate the absolute molecular weight. Light scattering measurements on [Fe(η⁵-C₅H₄)₂GeMe₂]ₙ gave a value of M_w = 3.3 × 10⁶ for the absolute molecular weight, whereas that obtained from GPC measurements was M_w = 8.2 × 10⁵. The underestimation of the molecular weight by the use of GPC was also reported for high molecular weight polygermanes. Starting from [1]germaferrocenophane, Fe(η⁵-C₅H₄)₂GeMe₂ (41) and the corresponding [1]silaferrocenophane, Fe(η⁵-C₅H₄)₂SiMe₂ (40), the random poly(ferrocenyl)dime-thylsilane–poly(ferrocenyl)dime-thylgermane copolymer was prepared by thermal ROP as well as by transition metal-catalysed polymerization (Scheme 23). Virtually the same silane–germane copolymer was reported by Tanaka and coworkers, who studied the influence of different palladium and platinum catalysts on the transition metal-catalysed homo- and copolymerization of Fe(η⁵-C₅H₄)₂GeMe₂ and Fe(η⁵-C₅H₄)₂SiMe₂ under mild conditions.

A one-pot synthesis of homo- and copolymers of ferrocenyl-dialkylgermanes starting from dilithioferrocene and the corresponding dichlorogermanes R₂GeCl₂ (R = Me, Et, n-Bu) was reported by Pannell and coworkers. The [1]germaferrocenophanes thus formed were heated at 140 °C without isolation prior to the thermal treatment. The polymers thus obtained had molecular weights lower than those reported for polyferrocenylgermanes prepared from purified [1]germaferrocenophanes.

Glass transition temperatures (T_g) for the poly(ferrocenyl)germanes are in a wide range of −7 to +124 °C and were found to depend on the nature of the substituents at germanium and the substituents at the cyclopentadienyl rings. Cyclovoltammetric measurements of
SCHEME 21. Synthesis of a poly(2,5-diphenylgermole)
the polymers show two oxidation waves, which is consistent with an electronic coupling of the iron centres. In contrast, poly(vinylferrocene) does not show any coupling of the ferrocenyl moieties. The UV-vis spectra of poly(ferrocenyl)germanes in solution showed $\lambda_{\text{max}}$ values of approximately 448 nm for both the homopolymers containing unsubstituted cyclopentadienyl rings and the germane–silane copolymer. The $\lambda_{\text{max}}$ values are close to those of ferrocene ($\lambda_{\text{max}} = 440$) and bis(trimethylgermyl)ferrocene ($\lambda_{\text{max}} = 444$ nm). The ferroenophane $[\text{Fe}(\eta^5-C_5H_4SiMe_3)_2\text{GeMe}_2]_n$ shows a bathochromic shift to $\lambda_{\text{max}} = 474$ nm, which is near the value observed for tetrakis(trimethylsilyl)ferrocene ($\lambda_{\text{max}} = 484$ nm).
iii. Synthesis of germanium containing copolymers by ‘oxidation–reduction copolymerization’. An alternative route to the conventional methods for the preparation of germanium-containing polymers, which is based on an oxidation–reduction process starting from stable germylenes, was introduced by Kobayashi and coworkers. Diorganogermylenes containing substituents such as methyl, ethyl or phenyl polymerise spontaneously to give polygermanes. Thermally stable, monomeric germylenes are accessible by the use of bulky substituents, which prevent the self-oligomerisation and/or polymerization. The appropriate choice of the substituents at germanium allows the corresponding germylene to act as a reducing species which copolymerises with various oxidizing monomers such as aldehydes, p-benzoquinone derivatives, cyclic α,β-unsaturated ketones and cyclic sulphides to give high molecular weight polymers (43–46) ($M_w > 10^5$) containing the germanium atoms in the main chain. The reactions proceed smoothly under mild conditions and usually give one-to-one periodic polymers. A two-to-one periodic polymer (45) was obtained by the reaction of cyclic bis-amidogermylenes and p-benzoquinone derivatives. The reaction of germylenes with benzoquinones or cyclic sulphides proceeds without the use of any catalyst, acid scavenger or dehydrating agent. The polymerization of α,β-unsaturated ketones with germylenes is catalysed by various lithium salts, but not by sodium salts or radical initiators such as tetramethylpiperidinyloxyl (TEMPO) or 2,2-azobis-iso-butyronitrile (AIBN).

![Chemical structures](#)

Compounds 43–46 are representative examples of the polymers prepared by the ‘oxidation–reduction copolymerization route’.

All polymers exhibit a periodic rather than a random distribution of the starting monomers in the polymer backbone. Nevertheless, for each class of these polymers a different reaction mechanism was proposed. In case of the reaction
of bis[bis(trimethylsilyl)amido]germanium with benzoquinone derivatives, a biradical propagation mechanism was established\textsuperscript{124}. In the copolymerization, polymeric germyl radicals were detected by ESR spectroscopy and were quenched with the radical scavenger TEMPO.

The copolymers \textit{43} obtained by the reaction of bis[bis(trimethylsilyl)amido]germanium with benzoquinone derivatives are thermally stable and melt without decomposition. However, generally they undergo hydrolysis in a THF–water solution. An exception is the 2,5-di-\textit{t}-butylhydroquinone copolymer, which is stable towards hydrolysis\textsuperscript{124}. A totally different mechanism was proposed for the copolymerization of bis[bis(trimethylsilyl)amido]germanium with cyclic propylene sulphide\textsuperscript{128} (Scheme 24). The first step is an oxidative insertion of the germylene into a C−S bond to give a germathietane \textit{47}, which is converted to germathione \textit{48} by a loss of propylene. The germathione \textit{48} is unstable and reacts via ring-opening with the episulphide to give the zwitterion \textit{49}. The propagation proceeds via successive combination among the zwitterions to give the regular one-to-one copolymer \textit{50} with a S−Ge−S sequence.

SCHEME 24. Proposed mechanism for the copolymerization of a propylene sulphide and bis[bis(trimethylsilyl)amido]germanium

The mechanism is only valid for systems which are capable of a propylene release. In contrast, the reactions of germynes with thietane gave regular one-to-one copolymers \textit{51} with a C−Ge−S sequence\textsuperscript{127} (Scheme 25).
The reaction mechanism proposed for the lithium-catalysed copolymerization of germylenes with cyclic ketones is based on the formation of germyl anions, which were formed by the coordination of the anion of the lithium salt to the germylene (Scheme 26). The germyl anion reacts with the ketone via a Michael-type addition to give an enolate anion. The latter enolate regenerates a germyl anion by reaction with the germylene. Alternating propagation leads to the regular one-to-one copolymer 52\textsuperscript{126,129}.

Polycarbogermane and polycarbostannane block copolymers \(56^{134}\) were prepared by pyrolysis of the organogermanium and organotin bridged \(p\)-cyclophanes \(55\) followed by deposition polymerization of the \(p\)-xylene monomers thus produced (Scheme 29).

C. Polymers Containing Tin in the Backbone

i. Polyferrocenylstannanes. In 1996, the synthesis of the first high molecular weight poly(ferrocenyl)stannane \([\text{Fe}(\eta^5-C_5H_4)_2\text{Sn(}t\text{-Bu})_2]_n\) \((58a)\) was reported by Manners and coworkers\(^{135}\). The polymer was obtained by ring-opening polymerization (ROP) of the \([1]\)stannaferrocenophane \(\text{Fe}(\eta^5-C_5H_4)_2\text{Sn(}t\text{-Bu})_2\) \((57a)\) (Scheme 30). Similarly, \([\text{Fe}(\eta^5-C_5H_4)_2\text{Sn(}2,4,6-(CH_3)_3C_6H_2)_2]_n\) \((58b)\) was prepared starting from the corresponding \([1]\)stannaferrocenophane \(57b^{136}\).

In principle, \([1]\)stannaferrocenophanes are promising candidates for ROP, although, as a result of the bigger covalent radius of tin, the ring strain is expected to be lower than in related silicon-containing derivatives. For \(57a\) the ring strain energy was estimated to be \(36(\pm 9) \text{ kJ mol}^{-1}\), which is approximately half of the value reported for organosilicon-bridged \([1]\)ferrocenophanes\(^{136}\). On the other hand, the bond between tin and the \textit{ipso}-carbon of the cyclopentadienyl ligand is weaker than in the corresponding \([1]\)silaferrocenophanes. High molecular weight polymers \(58a\) were obtained by thermally induced polymerization in the solid state \((M_w = 1.3 \times 10^5; M_w/M_n = 1.6)\) as well as in toluene solution at room temperature \((M_w = 9 \times 10^5; M_w/M_n = 1.6)\). The polymerization of \(57b\) proceeds significantly slower in comparison with the \(t\)-Bu2Sn-bridged analogue \(57a\), which can be explained by a lower ring strain energy of \(18(\pm 9) \text{ kJ mol}^{-1}\).
22. Organometallic polymers of germanium, tin and lead

Scheme 29. Polycarbogermane and polycarbostannane block copolymers

Scheme 30. Synthesis of poly(ferrocenyI)stannanes
of the former. Room-temperature ROP in benzene of 57b gave a high molecular weight polymer \( M_w = 1.35 \times 10^6 \); \( M_w/M_n = 1.3 \), but after 15 days only 50% of the monomers were converted. Thermal polymerization in the solid state of 57b quantitatively gave a lower molecular weight polymer \( M_w = 1.55 \times 10^5 \); \( M_w/M_n = 1.9 \). The [1]stannaferrocenophanes 57a and 57b both gave high yields of the cyclic dimer 59 when the ROP was carried out in CHCl₃.

![Diagram](image)

To date, the synthesis of strained [1]stannaferrocenophanes as precursors for ROP is restricted to compounds with bulky substituents at tin. Previous attempts to prepare tin-bridged ferrocenophanes by the reaction of dilithioferrocene with diorganotin dichlorides, \( \text{R}_2\text{SnCl}_2 \), containing less bulky substituents (\( \text{R} = \text{Me, Et, n-Bu, Ph} \)) resulted in the isolation of oligomers \( (M_n < 4.6 \times 10^3) \) and cyclic dimers. The crystal structure analyses of the [2]distannaferrocenophane 60 and the [3]tristannaferrocenophane 61, which are essentially unstrained, were also reported.

### ii. Homo- and heterobimetallic polycarbostannanes

Homometallic polycarbostannanes 63 were prepared starting from di(\( n \)-butyl)-di(4-pentenyl)stannane (62) via an acyclic diene metathesis reaction using both a molybdenum-alkylidene and an aryloxo tungsten catalyst (Scheme 31). Regardless of the catalyst, the polymerization proceeds smoothly and produces polymers with molecular weights of \( M_n = 1.6 \times 10^4 \) g mol\(^{-1} \). When the tungsten chloride catalyst is used, the organotin monomer simultaneously serves as cocatalyst and polymer precursor.

Similar to the synthesis of a germanium-containing poly(\( p \)-xylene) (PPX), the tin-containing block copolymer of unsubstituted PPX and a diorganotin bridged PPX were prepared (Scheme 29).

A heterobimetallic polycarbostannane 64 was obtained from the reaction of the bidentate \( \text{[Fe(CO)}_2\text{Cp–X–Cp(CO)}_2\text{Fe]}^{2–} \) \( (X = -\text{CHNM}_2\text{CHNM}_2{=}–) \) with \( \text{Ph}_2\text{SnCl}_2 \). The molecular weight as determined by osmometry was \( M_n = 8.5 \times 10^3 \) g mol\(^{-1} \), indicating relatively short chains. The reaction of the methylene-substituted dianionic...
iii. Organotin oxides. It is well established that diorganotin oxides (R₂SnO)ₙ, monooorganotin oxides (RSnO₁.₅)ₙ, and monooorganotin hydroxide oxides [RSn(OH)O]ₙ, containing small organic groups R such as Me, Et and n-Bu are polymeric, whereas bulky substituents stabilise oligomeric compounds. The polymeric stannoxanes are high-melting, insoluble, amorphous powders, the detailed structures of which are not known. On the basis of Mössbauer spectroscopy and solid state ¹¹⁹Sn NMR spectroscopy, the formation of cross-linked polymers containing five- and/or six-coordinate tin atoms was assumed.

iv. Polystannasiloxanes. Although metallasiloxanes containing Si–O–M linkages (M = main group as well as transition metals) are well known, reports on
polystannasiloxanes\textsuperscript{147–151} are rare. The synthesis of stannasiloxane block copolymers\textsuperscript{66} from sodium metasilicate $\text{Na}_2\text{SiO}_3$ and diorganotin compounds, such as di-$n$-butyltin oxide ($n$-$\text{Bu}_2\text{SnO}$), di-$n$-butyltin dimethoxide [$n$-$\text{Bu}_2\text{Sn(OMe)}_2$] and di-$n$-butyltin dichloride, were reported\textsuperscript{148} (Scheme 32). The silicon-to-tin ratio in the insoluble silicagel-like polymers varies in the range of 0.7–1.2 depending on the reaction conditions employed. On the basis of IR-spectroscopic measurements, the polymers were proposed to contain $\text{Si}–\text{O}–\text{Si}$, $\text{Si}–\text{O}–\text{Sn}$ and $\text{Sn}–\text{O}–\text{Sn}$ sequences.

\[
\text{Na}_2\text{SiO}_3 + n\text{-Bu}_2\text{SnX}_2 \rightarrow \begin{array}{c}
\text{Si} \begin{array}{c}O \\
\text{Sn} \begin{array}{c}O \\
\text{n-Bu} \\
\text{n-Bu}
\end{array}
\end{array}
\end{array}
\]

(Scheme 32. Synthesis of stannasiloxane block copolymers)

The first well-defined linear polystannasiloxane was reported in 1997. The reaction of $[\text{Ph}_2(\text{HO})\text{Si}]_2\text{O}$ with $t$-$\text{Bu}_2\text{SnCl}_2$ gave $[t$-$\text{Bu}_2\text{SnOSiPh}_2\text{OsiPh}_2\text{O}]_n$\textsuperscript{67} in high yield.

\[
[\text{Ph}_2(\text{HO})\text{Si}]_2\text{N} + t\text{-Bu}_2\text{SnCl}_2 \xrightarrow{\text{Et}_3\text{N}} 1/n[t\text{-Bu}_2\text{SnOSiPh}_2\text{OsiPh}_2\text{O}]_n
\]

A single crystal X-ray crystal structure analysis established a linear chain structure with both tin and silicon having tetrahedral configuration. In contrast to the polymeric structure found in the solid state, the stannasiloxane\textsuperscript{67} forms a six-membered ring in solution (Scheme 33).

\[
[t\text{-Bu}_2\text{SnOSiPh}_2\text{OsiPh}_2\text{O}]_n \rightarrow 1/n\begin{array}{c}
\text{Si} \begin{array}{c}O \\
\text{Sn} \begin{array}{c}O \\
\text{Ph} \\
\text{Ph}
\end{array}
\end{array}
\end{array}
\]

(Scheme 33. Structures of\textsuperscript{67} in the solid state and in solution)

III. POLYMER-SUPPORTED ORGANOTIN AND ORGANOGERMANIUM COMPOUNDS

Organotin compounds have become widely used reagents in organic syntheses\textsuperscript{83,86,88,152} which is a result of the special character of the tin–element bonds. For instance, tin–hydrogen, tin–oxygen and tin–carbon bonds are stable in air at room temperature but can be selectively cleaved under specific reaction conditions. Especially, organotin hydrides have become very popular reducing agents. Nevertheless, in recent years the toxicity of organotin and especially triorganotin compounds has been demonstrated\textsuperscript{153} which hampers the use of organotin reagents in the pharmaceutical industry and in
products which are potentially released into the environment. These drawbacks have initiated numerous attempts to prepare insoluble polymer-supported organotin reagents. The major advantage of these polymeric reagents is their easy separation from the reaction products. Thus, these compounds can be recovered and reconverted to the active tin species and their release to the environment is reduced to a minimum. A drawback of the heterogenous reaction is often the longer reaction time required compared with the analogous homogenous reaction. Furthermore, the structural characterization of the active tin sites inside the polymer is difficult to achieve.

Inorganic matrices and insoluble as well as soluble organic polymers are used as polymer supports (P). Recently, the applications of insoluble polymer-supported organotin reagents in organic synthesis have been reviewed\[154]. Other potential applications of polymer-supported organotin compounds include antifouling reagents, modifiers for rubbers used in tyre manufacturing and precursors for SnO₂. In contrast to organotin compounds, polymer-supported organogermainium compounds have attracted less attention and we are not aware of polymer-supported organolead compounds.

In this section new advances and novel synthetic methods, potential applications and structure elucidation techniques in the field of polymer-supported organotin and organogermainium compounds are presented.

**A. Polymer-supported Organotin Compounds**

1. **Syntheses**
   
   **i. Inorganic solid supports.** A promising approach to preparing insoluble organotin reagents which can easily be recovered by filtration is the anchoring of functionalised organotin compounds to inorganic matrices. The immobilised organotin reagents \[68\] and \[69\] were prepared starting from aluminium oxide and silica gel\[155,156\].

   \[
   \text{Si(OMe)_2(CH}_2 \text{)_5 SnBu}_2 \text{HOSiO}_2 \tag{69}
   \]

   \[
   \text{Si(OCH}_2 \text{)}_3 \text{SnBu}_2 \text{HOSiO}_2 \tag{68}
   \]

   The amount of active organotin hydride species in the \(\text{Al}_2\text{O}_3\) matrix (\[68\]), as determined by reaction with \(\text{CH}_3\text{I}\), was only 0.17 mmol g\(^{-1}\) \(\text{Al}_2\text{O}_3\) support\[155\]. Nevertheless, 1,1-dichloro-2,2-diphenylcyclopropane was almost quantitatively reduced to 1,1-diphenylcyclopropane. After recovering and reconveting the polymer-supported organotin halide into the corresponding organotin hydride \[68\] by reaction with diisobutyl aluminium hydride, the activity is almost halved with respect to the starting material. The silica-linked polymer \[69\] efficiently functions as an in situ prepared hydride transfer reagent for the reduction of carbonyl compounds using polymethylhydrosiloxane (PMHS) as hydrogen source\[156\]. After use and recovery of the polymer-supported organotin compound, no significant loss of activity was observed.

   **ii. The polymer resin functionalization route.** In contrast to the rather limited work on inorganic matrices as supports, the functionalization of a prebuild polymer was widely investigated. Usually, a cross-linked polystyrene is used as starting material and the organotin species are linked to the aryl groups of the polymer either directly or via alkyl spacers (Scheme 34).
An early example for the direct coupling of a tin reagent to Amberlite XE 305, a macroporous polystyrene, was reported by Crosby and coworkers\textsuperscript{157}. The synthetic route is shown in Scheme 35. Reaction of the polymer-supported diorganotin dihydride \textsuperscript{70} with iodoctane to give octane indicated a minimum content of 2 mmol tin hydride per gram of the polymer.

The polymer-supported organotin dihydride \textsuperscript{70} was shown to be an efficient reducing agent for aldehydes and ketones, but substantial loss of activity was observed after regeneration. More recently, various polymer-supported butyltin reagents (\textsuperscript{71}, \textsuperscript{72}) were studied as reagents for the acetylation of sucrose\textsuperscript{158}.

The polymer-supported butyltin dichloride was shown to catalyse the acetylation of sucrose to give 6-\textit{O}-acetyl sucrose in 59\% yield. The yield obtained was close to that previously reported for the same synthesis using (\textit{n}-Bu\textsubscript{2}SnO\textsubscript{n}) as catalyst\textsuperscript{159}. The polymer-supported organotin catalyst was regenerated without significant loss of activity by reaction with acetyl chloride. In contrast to (\textit{n}-Bu\textsubscript{2}SnO\textsubscript{n}) no regioselectivity towards acetylation of sucrose at the C-6 position was observed.

In polymer-supported organotin compounds the −CH\textsubscript{2}CH\textsubscript{2}− spacer has been widely used for the anchoring of active tin moieties to the polymer support. In contrast, the −CH\textsubscript{2}− spacer proved to be unsuitable, since the C−Sn bond of a stannyl group in the benzyl position is easily cleaved\textsuperscript{160−166}. A general method for the preparation of P−CH\textsubscript{2}CH\textsubscript{2}−SnBu\textsubscript{2}H starts from Amberlite XE 305, which is converted to P−CH\textsubscript{2}Cl

\[ \text{Scheme 34. Organotin-functionalised polystyrene} \]

\[ \text{Scheme 35. Synthesis of a polymer-supported diorganotin dihydride starting from Amberlite XE 305} \]
by chloromethylation. Wittig-type vinylation was used to prepare \( \text{P-CH=CH}_2 \), followed by hydrostannation with Bu\(_2\)SnHCl to give \( \text{P-CH}_2\text{CH}_2\text{SnBu}_2\text{Cl} \). The tin chloride was transformed to \( \text{P-CH}_2\text{CH}_2\text{SnBu}_2\text{H} \) by reaction with LiAlH\(_4\). This rather specific route is limited to the \(-\text{CH}_2\text{CH}_2-\) spacer and therefore a more convenient and general reaction sequence was developed by Dumartin and coworkers\(^{167,168}\) (Scheme 36). They prepared polymer-supported organotin hydrides in which the stannyl group is linked to the polymer via methylene spacers of various lengths. The functionalised polystyrenes were prepared from lithiated Amberlite XE 305, which was reacted either with Br(CH\(_2\))\(_n\)Cl \((n = 3, 4)\) or with ethylene oxide \((n = 2)\), followed by halogenation with PPh\(_3\)/CCl\(_4\) or Me\(_3\)SiCl/NaI. The polymer-supported halogenoalkanes \(73\) were transformed into the polymer-supported tin hydrides \(75\) by reaction with Bu\(_2\)SnHLi. An alternative route is the reaction of \(73\) with (i) Bu\(_2\)SnPhLi and (ii) I\(_2\) to give the polymer-supported tin iodide \(74\), which in turn reacts with NaBH\(_4\) to give \(75\).

\[
\begin{align*}
\text{Amberlite XE 305} & \quad \xrightarrow{\text{BuLi, TMEDA}} \quad \text{P} \quad \xrightarrow{\text{Li}} \quad \text{P} \\
\text{Br(CH\(_2\))\(_n\)Cl} & \quad \xrightarrow{n = 3,4} \quad \text{P} \quad \xrightarrow{\text{i) PPh\(_3\)/CCl\(_4\)}} \quad \text{P} \\
\text{P} \quad \xrightarrow{(\text{CH\(_2\)))\(_n\)SnBu\(_2\)H} & \quad \xrightarrow{\text{Bu\(_2\)SnHLi}} \quad \text{P} \\
\text{NaBH\(_4\)/EtOH} & \quad \xrightarrow{\text{i) Bu\(_2\)SnPhLi}} \quad \text{P} \\
\text{P} \quad \xrightarrow{(\text{CH\(_2\)))\(_n\)SnBu\(_2\)I} & \quad \xrightarrow{\text{ii) I\(_2\)}} \quad \text{P} \\
\end{align*}
\]

**SCHEME 36. Synthesis of polymer-supported tin hydrides**

The minimal tin loadings of the polymer supported tin hydrides \(75\) were found to be in the range of 0.9–1.4 mmol SnH g\(^{-1}\), which is comparable with the activity of the polymer-supported and \(-\text{CH}_2\text{CH}_2-\) linked dibutyltin hydride reported by Neumann and coworkers\(^{160,169}\). The advantage of the use of alkyl sequences longer than the \(-\text{CH}_2\text{CH}_2-\) spacer is the prevention of \(\beta\)-elimination in free-radical processes.

**iii. The monomer polymerization route.** Compared with the resin-functionalization route, the homo- and copolymerization of organotin-containing monomers permits one to influence the polymer resin structure to a greater extent. In principle, it is possible to prepare gel-type, macroporous, microporous or nonporous polymers. The pore structure, tin loading, solubility and other factors which influence the reactivity of the polymer-supported organotin reagents can be controlled by appropriate
copolymorization processes of carefully chosen monomers. Thus, physical properties of organotin-containing polymers, being important for materials applications, can be fine-tuned. In order to mimic the properties of commercial macroporous polystyrenes such as Amberlite XE 305, the copolymerization of monomeric tin-containing styrene derivatives and divinylbenzene were carried out. Neumann and coworkers copolymerised [(2-vinylphenyl)ethyl]dibutyltin chloride and divinylbenzene (ca 10%) to prepare the macroporous cross-linked polymer, which was converted into the polymer-supported tin hydride by using di-n-butylaluminium hydride. A tin-loading of 1.55 mmol SnH g$^{-1}$ was obtained for the polymer. The copolymerisation of [(2-vinylphenyl)ethyl]triphenyltin with vinyl-containing comonomers in the presence of divinylbenzene was also reported. The triphenyltin-containing polymer was chemically modified to give functionalised polymer-supported organotin compounds of type $\text{P(}\text{CH}_2\text{)}_2\text{SnBu}_2\text{X}$

A mixture of $m$- and $p$-substituted [(2-di-n-butylchlorostannyl)ethyl]styrene was copolymerised with different amounts of styrene and a mixture of $m$- and $p$-substituted divinylbenzene (Scheme 37). The copolymers are granular colourless solids, which are insoluble but swellable in both protic and aprotic solvents. The proportions of the organotin monomer used in the starting reaction mixtures corresponded to 94, 73 and 25 wt%. The values of the monomeric units in the polymers as estimated by argentometric titration (Cl/g polymer) were lower than expected and were found to be 68, 46 and 10 wt% (yield 50–75 wt%). Under the reaction conditions employed, the organotin monomer is not quantitatively incorporated into the polymer matrix. Deleuze and coworkers examined the copolymerization of the same system, but used pure isomers of $p$-[(2-di-n-butylchlorostannyl)ethyl]styrene and $p$-divinylbenzene or $m$-divinylbenzene instead. The resulting tin-loading of the polymer was much closer to the monomer ratio in the reaction mixtures than that reported for the copolymerization of mixed isomers. The high permanent porosity of the supports obtained enable the polymer-supported organotin chlorides to reduce 1-bromoadamantane using NaBH₄ as hydride source. The reactivity of the polymer-supported organotin chloride is comparable with that of tributyltin chloride. The polymer-supported organotin chloride exhibits a relative high intrinsic stability, as was shown by several uses without loss of activity and without need of regeneration.

The polymer was reacted with sodium hydroxide in EtOH/H₂O to give a mixture of stannol and distannoxane moieties in ratios depending on the tin-loading capacities of the starting polymers. The ratio was not changed upon heating at reflux the polymer in a benzene/water mixture. The trend of decreasing distannoxane-to-stannol ratio with decreasing tin-loading capacity is in accordance with a lower ‘effective concentration’ of the tin monomers in the copolymer as a result of dilution with styrene. Two stannol moieties, which are close to one another, can form distannoxanes by a condensation reaction, whereas isolated stannols remain unchanged. The reaction of the polymer-supported di-n-butyltin chloride with sodium 4-methylbenzoate was also reported. The resulting tethered carboxylate displayed poor stability and reacted under protic conditions to give 4-methylbenzoic acid. Tributyltin-3-$p$-vinylphenylpropionate (TBTSP)
SCHEME 37. A monomer polymerization route to polymer-supported organotin reagents

(83) was homo- and copolymerised with styrene, affording polymer-supported organotin compounds in which a tributyltin moiety is linked via a carboxylate group to a polystyrenic support.
The homopolymerization of 83 gave a soluble polymer of relatively low molecular mass \( M_n = 8.4 \times 10^3 \), but the average molecular weight increased with increasing content of styrene co-units in the copolymer. For a TBTSP-to-styrene ratio of one-to-four, a polymer with \( M_n = 1.5 \times 10^4 \) was obtained.

Other trialkyltin-containing monomers such as 3-tributyltinstyrene (84), tributyltin methacrylate (85) and \{4-[bis(trimethylstannyl)methyl]styrene\} (86) were also reported to homo- and copolymerise with styrene under radical conditions. In addition, 3-tributyltinstyrene (84) was copolymerised under radical conditions with ethyl acrylate, methyl methacrylate, vinyl acetate and acrylonitrile. A functional methacrylate-based polymer was prepared by the copolymerization of the triorganotin methacrylate monomer 87 with styrene and divinylbenzene.

In order to prepare non-styrenic polymer-supported organotin chlorides, which are expected to show physical properties such as mechanical strength, polarity and porosity different from those of polystyrene-based supports, Deleuze and coworkers copolymerised dibutyl[3-(allyloxy)propyl]tin chloride with N-phenylmaleimide (PMI) and 1,1′-(methylene-4,1-phenylene)bismaleimide (MPBMI) to prepare the polymers 88a and 88b.

\end{align*}
\]
It turned out that the insertion of the organotin compound into the polymer 88a did not exceed 16 mol%, regardless of the monomer feed. Various insoluble polymers 88b were prepared by the radical copolymerization of dibutyl[3-(allyloxy)propyl]tin chloride, PMI, as a chain diluent, and MPBMI as cross-linking agent. These polymers exhibited higher swelling capacities in toluene than those of macroporous organotin-functionalised polystyrene resins\textsuperscript{174}. The rather low specific surface areas as determined by BET analyses were in the range of 3–23 m\textsuperscript{2} g\textsuperscript{−1} indicating the polymer structure to be more gel-type than expected, which in turn is the result of the poor cross-linking ability of the bismaleimide under the polymerization conditions employed. The activity of the polymer-supported organotin chloride 88b was demonstrated in the reduction of 1-bromoadamantane using NaBH\textsubscript{4} as primary hydride source. The polymer could be recycled and used several times without significant loss of activity. A drawback was the relatively high extent of tin-leaching during the reduction process (ca 0.5–0.8% per run), which was attributed to the high reaction temperatures of 95 °C.

\textit{iv. Anionic polymerization.} Anionic oligomerization of ethylene or styrene followed by electrophilic substitution of the resulting anionic polymer with tin halides such as tin tetrachloride, \textit{n}-butyltin trichloride, \textit{di}-\textit{n}-butyltin dichloride and diphenyltin dichloride, respectively, was reported\textsuperscript{181}. The resulting linear macromolecules which are soluble in common organic solvents contain organotin moieties at one chain end. In a typical synthetic procedure, the oligomerization of ethylene with \textit{n}-butyllithium as initiator was followed by treatment of the resulting suspension of living polyethylene with \textit{di}-\textit{n}-butyltin dichloride at −78 °C. The product was separated from any insoluble by-products by extraction with hot toluene. Similarly, tin-containing polybutadiene and polystyrene–polybutadiene copolymers were prepared by anionic polymerization and with trialkyltin chlorides as end-capping reagents, giving tin-modified rubbers which are used for tyre manufacturing\textsuperscript{182–186}. 

(88b)
2. Applications

i. Organic synthesis. As a result of both the economical and ecological considerations mentioned before, organic syntheses on solid phases have become an established method for synthetic organic transformations\textsuperscript{187}. Polymer-supported organotin reagents were shown to be as efficient as their soluble counterparts in various organic transformations. The advantages of the polymer-supported reagents are that (i) the amount of toxic organotin species released into the environment is minimised and (ii) the reagents can easily be separated from the reaction mixtures and regenerated for repeated use. On the other hand, depending on the nature of the support, longer reaction times are often required as a result of diffusion-controlled reactions. The most common reaction to test the practical value of polymer-supported organotin hydride reagents is the dehalogenation of alkyl halides. The results are compared with those obtained by the use of Bu$_3$SnH as a soluble hydride transfer reagent. After the reaction, the polymer is recovered, regenerated and used again in the same standard reaction\textsuperscript{154,167–169,174,180} (Scheme 38).

\[ \text{Scheme 38. Test for multiple use of polymer-supported organotin hydrides} \]

A variety of other alkyl and aryl halides were successfully dehalogenated by polymer-supported organotin hydrides even in the presence of functional groups\textsuperscript{155,157,160,168,169,181,188}. Two representative examples are shown in Scheme 39.

\[ \text{Scheme 39. Dehalogenations using a polystyrene-supported tin hydride (P-SnH)\textsuperscript{169}} \]
The dehalogenations of 3-bromocamphor and 1-bromoadamantane were reported to be efficient both by using a triorganotin hydride which is linked to the polymer support via a \(-\text{CH}_2\text{CH}_2-\) spacer\(^{169}\), and by using a diorganotin dihydride, which is directly bound to the support\(^{157}\). The latter reagent showed significant loss of activity (40%) after regeneration whereas the former was used repeatedly without loss of activity. The polymer-supported diorganotin dihydride was also shown to reduce aldehydes and ketones. For example, benzaldehyde was converted into benzyl alcohol in a 91% yield. However, in this case the regeneration appeared to be even worse as compared with the reduction process of organic halides. Only 30% of the diorganotin dihydride content was regenerated and decomposition of the polymer-supported tin compound was observed\(^{157}\).

Polystyrene-supported organotin hydrides were successfully used in the dehydroxylation of various secondary alcohols according to the Barton-type reaction\(^{160,169,189}\). The secondary hydroxyl group is transformed into a thiono group, which in turn is reduced by the organotin hydride reagent in a free-radical chain reaction to give the corresponding alkane. The synthesis of 5-cholestene is given as an example in Scheme 40. The polymer-supported organotin hydride \(\text{P-CH}_2\text{CH}_2-\text{SnBu}_2\text{H}\) is an excellent substitute for the Bu\(_3\)SnH usually used in such reactions.

The same polymer-supported organotin reagent was also used in the Barton-type deoxygenation of steroid derivatives, sugar derivatives and diols\(^{160}\). Furthermore, the radical deamination of secondary and tertiary amines via the corresponding isocyanides was also reported\(^{160,169}\).

The search for other reactions in which a polymer-supported organotin hydride is capable of substituting Bu\(_3\)SnH as radical source has led to the application of \(\text{P-CH}_2\text{CH}_2-\text{SnBu}_2\text{H}\) for the ring enlargement of dichloromethylcyclohexadienones. Two out of twelve examples\(^{190}\) for the preparation of tropone ring systems are shown in Scheme 41.

The Giese-type reaction is another example for a free-radical reaction in which Bu\(_3\)SnH was replaced by a polymer-supported organotin hydride. The free-radical chain coupling of alkyl and aryl radicals with electron-deficient olefins requires a low stationary concentration of the organotin hydride. The carbon–carbon coupling reaction of cyclohexyl halides with acrylonitrile was carried out to give cycloC\(_6\)H\(_{11}\)(CH\(_2\))\(_2\)CN, being almost free of tin by-products\(^{165}\), but the conversion rates were rather low when compared with conventional methods using Bu\(_3\)SnH. The best results were obtained when the polymer-supported organotin hydride was generated \textit{in situ} and in a low steady-state concentration from the corresponding polymer-supported organotin chloride and NaBH\(_4\). The \textit{in situ} preparation of polymer-supported organotin hydrides starting from the corresponding organotin chloride and sodium borohydride was also applied for the reduction of 1-bromoadamantane (activity test)\(^{174}\) and for the synthesis of 2-alkoxytetrahydrofuranes\(^{178,179}\). The latter synthesis started from bromoacetals and the intramolecular radical cyclization gave tetrahydrofuran derivatives, which in turn are precursors for \(\gamma\)-butyrolactones (Scheme 42).

Organotin hydrides are used to generate stannyl radicals, which in turn initiate radical chain reactions. However, the presence of high contents of organotin hydrides in the reaction mixture can be disadvantageous since tin hydrides are known to be strong radical scavengers. Neumann and coworkers suggested the use of polymer-supported distannanes\(^{164,166}\) as radical source to circumvent this problem. Polymer-supported distannanes \(\text{90}\) with tin loadings of 0.95–1.13 mmol g\(^{-1}\) were prepared by treatment of the organotin halide resins \(\text{89}\) with lithium naphthalenide and sodium naphthalenide\(^{166}\).
SCHEME 40. Barton-type deoxygenation using a polymer-supported organotin hydride
SCHEME 41. Ring enlargement of dichloromethylcyclohexadienones using a polymer-supported organotin reagent

SCHEME 42. Intramolecular radical carbocyclisations to give furan derivatives

respectively (Scheme 43). These reducing agents proved to be superior to the initially used magnesium-anthracene. The polymer-supported distannane was used as a source of stannyl radicals in several radical cyclization reactions, such as the photochemical radical chain addition of \( t \)-butyl iodide to acetylenes yielding the \( Z/E \) mixture of alkenes or the photochemical cyclization of citronellyl bromide to give menthane in high yields (Scheme 44).

The one-step preparation of \( \gamma \)-butyrolactones starting from an acyclic \( \alpha \)-iodo ester was also investigated by using the polymer-supported distannane as radical source. The \( \gamma \)-butyrolactone was formed in 35% yield and contained 61% of the reduced \( \alpha \)-haloester (Scheme 45).

The palladium-catalysed carbon–carbon cross-coupling reaction of organotin reagents with a variety of organic electrophiles has found various synthetic applications (the Stille reaction). Usually, only one organic group from the tetraorganotin reagent is
SCHEME 43. Preparation of the polymer-supported distannane 90

$R = \text{alkyl}$

$R' = \text{alkyl, vinyl, aryl, alkynyl}$

$R'' = \text{allyl, vinyl, aryl}$

**SCHEME 46.** The Stille-type reaction

A major drawback of this reaction is the formation of equimolar amounts of rather toxic trialkyltin by-products. Kuhn and Neumann investigated polystyrene-supported tin reagents for the Stille-type reaction\textsuperscript{163}. Therefore, immobilised organotin chlorides ($91a$) and hydrides ($91b$) were transformed to polymer-supported Stille-type reagents by reaction of the polymer-supported organotin chlorides $91$ with various Grignard reagents or by hydrostannation reactions of the polymer-supported organotin hydrides with terminal alkynes, respectively (Scheme 47). The polymer-supported reagents $92$ and $93$ were used successfully in the Stille-type coupling with electrophiles such as acyl chlorides, vinyl iodides and vinyl triflates\textsuperscript{163}.

**SCHEME 47.** Polymer-supported Stille-type reagents

A polymer-supported allyltin derivative was also reported to undergo a Lewis-acid-catalysed addition to benzaldehydes to give products such as 1-phenylbut-3-en-1-ol and 1-($p$-bromophenyl)but-3-en-1-ol\textsuperscript{154}.

The polymer-supported random stannol/stannoxane copolymer $94$ was shown to catalyse the lactonisation of hydroxycarboxylic acids\textsuperscript{170}. 

$$\text{P} - \xrightarrow{(CH_2)_2} \text{Sn} \rightarrow \text{Bu}$$

a: $X = \text{Cl}$

b: $X = \text{H}$

$$\text{P} - \xrightarrow{(CH_2)_2} \text{Sn} \rightarrow \text{R} \rightarrow \text{Bu}$$

$$\text{P} - \xrightarrow{(CH_2)_2} \text{Sn} \rightarrow \text{CH} = \text{CH} \rightarrow \text{R}' \rightarrow \text{Bu}$$

$R = \text{C} \equiv \text{CPh}, \text{CH} = \text{CH}_2, \text{CH} \equiv \text{CHCH}_3$

$R' = \text{CO}_2\text{Me}, \text{CO}_2\text{H}$
While the optimal yields of the isolated lactones were comparable with the yields obtained using conventional tin-based catalysts such as hexa–n-butyldistannoxane, n-dibutyltin oxide, tri–n-butylcholorostannane or tri–n-butylmethoxystannane, the solid phase reaction offers the advantage of a simplified purification procedure\(^{170}\). The catalytic trans-esterification using solid polymer-supported organotin alkoxides was also reported\(^{171}\). The catalyst could be recovered without significant loss of activity or leaching of organotin compounds from the polymers.

**ii. Radiopharmaceuticals.** Radiopharmaceuticals are drugs which contain unstable nuclei emitting particles or photons. They are used as imaging agents for diagnostic purpose and in radiotherapy of various diseases. Triorganotinal and -vinyl compounds are selectively cleaved by iodine to give iodoaryls and iodoxynils under fairly mild conditions, making organotin reagents promising precursors to prepare pharmaceuticals containing radioactive iodine isotopes. However, the complete removal of the toxic triorganotin by-products from the pharmaceutical product is a serious problem difficult to overcome by conventional separation techniques. Therefore, the use of polymer-supported organotin reagents as intermediates in the synthesis of radiopharmaceuticals was examined\(^{154,192–198}\). In principle, the organic precursor is anchored to the polymer support via the triorganotin moiety and in a subsequent step the radiopharmaceutical is released into solution by tin–carbon bond cleavage. Radioiodinated vinyl iodides were prepared by reaction of the polymer-supported organotin hydride \(\text{P}–\text{CH}_2\text{CH}_2–\text{SnBu}_2\text{H}\) with terminal alkynes to give the polymer-supported tin vinyl compounds \(\text{P}–\text{CH}_2\text{CH}_2–\text{SnBu}_2\text{Vinyl}\), subsequently followed by radio-demetallation of the latter with \(\text{Na}^{125}\text{I}\) and chloramine T as oxidant\(^{197}\). Similarly, the polymer-supported organotin hydride \(\text{P}–(\text{CH}_2)_4–\text{SnBu}_2\text{H}\) was used in reaction sequences to study the iodo-demetallation reaction of polymer-bound pharmaceuticals\(^{152,154,193}\). Four representative examples of radioactive substances prepared via polymer-supported organotin compounds are given below.

Hunter and coworkers started from the polymer-supported organotin chloride \(^{95}\), which was reacted with aryllithium compounds to give precursors for radioiodinated pharmaceuticals\(^{192,195,196,198}\).

The syntheses of \(^{123}\text{I}-\) and \(^{131}\text{I}-\)labelled \(\text{N}\)-isopropyl-4-idoamphetamine and \(^{123}\text{I}\)-labelled \(\text{m}\)-iodobenzylguanidinium, \([^{123}\text{I}]{\text{MIBG}}\), were reported. The synthesis of \([^{123}\text{I}]{\text{MIBG}}\) \(^{192}\), which has found application in nuclear medicine either as an imaging agent for diagnosis or as a therapeutic agent for neutral crest tumors, is shown in Scheme 48.

**iii. Applications in tyre manufacturing.** Two important properties of tyres are the so-called rolling resistance and the wet grip, which both depend on the physical characteristics
of the polymeric material used in the manufacturing process. The properties of some organotin-containing polymers have recently been investigated, since the incorporation of organotin groups changes the performance characteristics of elastomers used for tyres. Among these polymers, tin-containing polybutadiene and styrene–butadiene copolymers have attracted most attention\(^\text{182–186,199}\), but in addition derivatives such as polyisoprene and \(\alpha\)-methylstyrene were also investigated\(^\text{182}\). In a typical synthetic procedure, living anionic polymerization of 1,3-butadiene or 1,3-butadiene/styrene mixtures was followed by the addition of various tin chlorides. Tributyltin chloride was added in order to end-cap the polymer chains, whereas the addition of tin tetrachloride provided star-shaped polymer structures. The latter process was followed either by addition of trialkyltin chlorides to end-cap the polymers with trialkyltin groups or by addition of an antioxidant to terminate the polymerization and to end-cap the polymers with methyl groups\(^\text{182}\). One-dimensional \(^{119}\)Sn NMR and \(^1\)H/\(^{13}\)C/\(^{119}\)Sn triple-resonance three-dimensional NMR studies of organotin-containing polybutadienes were carried out to provide information on the microstructure of the organotin-containing polymers\(^\text{183,184,199}\).

**iv. Tin dioxide formation.** Tin dioxide, \(\text{SnO}_2\), is a promising material for light-transmitting electrodes in optoelectronic devices as a result of its optical transparency and its electronic conductivity. Furthermore, the high chemical stability of \(\text{SnO}_2\) makes it a valuable coating material. On the other hand, its high chemical stability prevents patterning of \(\text{SnO}_2\) thin films by wet etching. Starting from various precursors, dip-coating followed by hydrolysis, chemical vapour deposition, spray pyrolysis and sputtering are suitable methods for the preparation of \(\text{SnO}_2\) thin films. Alternatively, soluble organotin polymers are promising precursors for the preparation of \(\text{SnO}_2\) thin films and their use was suggested to solve the problem of patterning by lithographic techniques\(^\text{177,200–202}\). For example, a thin film of poly\{4-[(trimethylstannyl)methyl]styrene (96)\} was spincoated on quartz plates from its toluene solution, dried, irradiated and pyrolysed to give a \(\text{SnO}_2\) thin film without any cracks or peeling\(^\text{202}\). In contrast, pyrolysis of the same polystyrene derivative without irradiation did not give \(\text{SnO}_2\), but low molecular weight organotin compounds which escaped from the quartz plate by evaporation.
SCHEME 48. Synthesis of $^{[131]}$MIBG via the polymer-supported organotin chloride.
It was suggested that the irradiation causes homolytic cleavage of the benzylic Sn−C bonds in 96 giving rise to formation of a cross-linked organic network. This network is insoluble and tin species are thought to be trapped in it. Upon heating, the cross-linked polymer film functions as a matrix for the organotin precursors of SnO₂ and is completely removed after pyrolysis (Scheme 49).

\[
\text{SnMe}_3 \xrightarrow{\Delta} \text{SnO}_2 + \text{cross-linked network + tin species}
\]

SCHEME 49. Preparation of SnO₂ via poly[4-[(trimethylstannyl)methyl]styrene (96)

3. Leaching of organotin compounds

As mentioned before, the toxicity of organotin compounds is the major drawback of organotin reagents and, despite its synthetic utility, it prevents its entry to the pharmaceutical industry and questions the application of organotin compounds in products from which they can be released into the environment. Polymer-supported organotin reagents are suggested to reduce the tin contamination of the final products almost to zero. Without any doubt, the tin contamination of products prepared by using immobilised organotin reagents is very low when compared with the same product prepared by the use of a soluble organotin reagent, e.g. the reduction of 3-iodocholestene (1.45 mmol) with Bu₃SnH gave 5-cholestene in 75% isolated yield after one recrystallization. The 5-cholestene was highly contaminated with tin (7000 ppm). In order to reduce this contamination to 45 ppm, four recrystallization cycles were needed. Using the polymer supported tin hydride \( P-(CH_2)_4-SnBu_2H \) instead, 5-cholestene was isolated in 60% yield with a residual tin contamination of approximately 45 ppm without the need of recrystallization. Junggebauer and Neumann reported the photochemically initiated cyclization of acyclic \( \alpha \)-haloester to give \( \gamma \)-butyrolactones using the polymer-supported distannane 90 in which the distannane units function as radical source. The tin contamination of the cyclization products was evaluated by Atomic Absorption Spectroscopy (AAS). Depending on the temperature and the time of irradiation with UV light, tin contaminations in the range of 150–1100 ppm were detected, which is much too high for applications under the purity standards required for pharmaceutical products. Nevertheless, photochemical reactions using Bu₆Sn₂ gave even significantly higher values of tin contamination.

The non-styrenic macroporous polymer-supported organotin chloride 88b showed good activity in the catalytic reduction of 1-bromoadamantane with sodium borohydride as primary hydride source. The reagent was used several times and showed substantial tin leaching, which was estimated by AAS to be 0.3–1.2% of the initial tin content per run. The leaching of tin increased with increasing temperature.
polymer-supported organotin halides $\text{P}−(\text{CH}_2)_4−\text{SnBu}_2\text{I}$ and $\text{P}−(\text{CH}_2)_2−\text{SnBu}_2\text{Cl}$\textsuperscript{204}. The $\text{P}−(\text{CH}_2)_4−\text{SnBu}_2\text{I}/\text{NaBH}_4$ system was the most efficient one when the amount of halide was kept in the range of 0.2–0.9 equivalents, and isolated yields of adamantane of about 90\% were obtained. Very low levels of tin pollution (<35 ppm) in the adamantane were observed by ICP-MS measurements, reaching values which were identical to blank experiments for low tin halide-to-$\text{NaBH}_4$ ratios. The residual tin contamination in adamantane which was prepared with the system $\text{P}−(\text{CH}_2)_2−\text{SnBu}_2\text{Cl}/\text{NaBH}_4$ was significantly higher (1975 ppm). The highest tin contamination of adamantane was observed when the $\text{Bu}_3\text{SnCl}/\text{NaBH}_4$ system was used. Even after purification of the adamantane by flash chromatography or treatment with potassium fluoride solution, a residual tin content of about $10^5$ ppm was detected.

In addition to the chemical degradation of polymer-supported organotin reagents, the mechanical abrasion of the polymer beads is another origin of organotin contamination of the products. It is also possible that the polymer resin contains organotin compounds which were incorporated during the synthesis of the polymer-supported reagent and which were not completely separated from the polymer resin despite careful purification. The preparation of non-polluting organotin reagents for applications in organic syntheses remains a challenging target.

4. Characterization

To date, several applications of polymer-supported organotin compounds were reported but for further developments it is essential to get a better insight into the microstructure of the polymers and the nature of the organotin functionalities anchored to the polymer. The elemental analysis is still a standard and essential method to elucidate the composition of the polymer. In addition, energy-dispersive X-ray analysis (EDX) was performed on polymer-supported organotin chlorides in order to determine the tin-to-chloride ratio. Mainly gel permeation chromatography (GPC) was used to determine the average molecular weights of soluble polymer-supported organotin compounds\textsuperscript{172,177,182,185,186,201,202}. An alternative method to estimate the average molecular weight of polymers is the measurement of intrinsic viscosities\textsuperscript{176}. The thermal behaviour of polymers, which is a crucial property for applications in materials science, was investigated by means of thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC)\textsuperscript{172,175−177,182,185,186,201,202}. Polymer-supported reagents containing functional organotin moieties such as $\text{Sn}−\text{H}$ or $\text{Sn}−\text{OOCR}$ were characterised by infrared spectroscopy (IR)\textsuperscript{157,167,168,172,205}. For $\text{Sn}−\text{H}$ containing polymer-supported reagents, the tin hydride loading of the polymer was determined by test reactions with haloalkanes such as methyl iodide, 1-bromoadamantane or 1-bromoocane\textsuperscript{155,157,162,167,168,205}. Determination of the quantity of the alkanes thus formed is an indirect measure for the minimum tin hydride content of the polymer, provided that the reaction is quantitative. The effective tin hydride loading usually differs from the total tin loading and even from the real tin hydride loading. The latter can be higher than the value determined by the test reaction. This divergence is a result of the tin hydride sites being located in the polymer matrix and hence being not accessible because of diffusion problems. The specific surface area as estimated by the Brunauer, Emmet and Teller (BET) nitrogen adsorption method is valuable to provide information on the pore structure of the polymer and the potential accessibility of functional groups inside the polymer network\textsuperscript{174,180}.

One-dimensional $^{119}\text{Sn}$ NMR spectroscopy in solution was used to characterise soluble polymer-supported organotin compounds\textsuperscript{181,199}. To get a more detailed understanding of the microstructure of tin-containing polymers, $^1\text{H}/^{13}\text{C}/^{119}\text{Sn}$ triple resonance 3D NMR
experiments of polybutadienes containing tributyltin groups at the chain ends were carried out\(^{183,184}\). The combination of 1D, 2D and 3D NMR experiments allowed a detailed assignment of all \(^1H\), \(^{13}C\) and \(^{119}Sn\) NMR signals of the different structures observed. Based on the chemical shift assignment it was possible to quantify the amount of each structure. After the identification of the atomic connectivity patterns, the chain end monomer distribution can be extracted from quantitative \(^{13}C\) NMR spectra. It was pointed out that this 3D NMR technique is applicable to the structural characterization of organotin compounds, even when isotopic labelling is not possible for compounds having nuclei of low natural abundance and despite the extremely low concentration of the species in a polymer matrix.

One-dimensional solid state \(^{117}Sn\) and \(^{119}Sn\) NMR were used to get qualitative information on the organotin functionalities anchored to insoluble polymers\(^{170,172,205}\). Under certain conditions also quantitative information was deduced from solid state \(^{117}Sn\) NMR. However, this required a careful choice and setting of the acquisition conditions\(^{205}\). The quantification of relative amounts of different tin species in a polymer matrix was reliable within 10%. For example, the polymer \(P-(\text{CH}_2)_6-SnBu_2H\) was prepared from the corresponding tin iodide \(P-(\text{CH}_2)_6-SnBu_2I\) by reduction with NaBH\(_4\). From the integrals of the \(^{117}Sn\) NMR signals assigned to the Sn–H and Sn–O–Sn functionalities, the SnH-to-Sn\(_{\text{total}}\) ratio was estimated to be approximately 58\%. To check this result, the total amount of tin was determined by elemental analysis and the tin hydride content was estimated by a test reaction with 1-bromodecane. The resulting SnH-to-Sn\(_{\text{total}}\) ratio of 54\% was in good agreement with the ratio estimated from the \(^{117}Sn\) NMR CP-MAS spectra.

Further developments in the field of insoluble polymer-supported organotin compounds will be accompanied by the expansion of solid state tin NMR data and the development of new NMR techniques. In Table 8, some representative examples of \(^{117}Sn\) and \(^{119}Sn\) NMR chemical shifts of polymer-supported organotin compounds are given.

\(^a\) R = alkyl groups similar to the \(n\)-Bu group, but not defined in the original publication.

\(^b\) Slightly different chemical shifts were observed depending on the nature of the polymer support.

\(^c\) Ar = \(p\)-CH\(_3\)C\(_6\)H\(_4\).

\(^d\) Two signals were observed as a result of tetra- and pentacoordinated tin atoms in the polymer matrix.
B. Polymer-supported Organogermanium Compounds

1. Polymer-supported reagents

Organogermanium compounds are known to be non-toxic, which makes them attractive as reagents in organic syntheses. However, the high price of germanium is a disadvantage and consequently reactions involving organogermanium reagents are only economic if the latter can be completely recovered from the reaction mixtures. A promising strategy to address this problem is the development of polymer-supported germanium reagents. Thus, the use of polymer-supported organogermanium hydrides as substitutes for polymer-supported organotin hydrides as reducing agents for organic halides was suggested. Three examples of polymer-supported germanium hydrides are presented in Scheme 50.

SCHEME 50. Synthesis of polymer-supported organogermanium hydrides

The polystyrene-supported organogermanium hydrides were characterised by solid state NMR, IR (\(\nu\ \text{Ge}--\text{H} 2000–2018\ \text{cm}^{-1}\)) and X-ray photoelectron spectroscopy (XPS) (Ge content 3.8–4.0 mmol g\(^{-1}\); degree of functionalization 0.28–0.30)\(^{206}\). Several octyl and phenyl halides were reduced by the polymer-supported organogermanium reagents simply by heating the corresponding reaction mixtures with free-radical initiators. The reactivity of the germanium hydrides increased with increasing chain length of the \((\text{CH}_2)_n\)-spacer. The best results were obtained for the reduction of 1-octyl bromide and 1-octyl iodide with P–(CH\(_2\))\(_2\)–GeEt\(_2\)H (99). Gas chromatography indicated that octane was formed in 60% yield. In addition, polyhalobenzenes were reduced stepwise, e.g. 1-bromo-2-chlorobenzene was reduced to 1-chlorobenzene in 22% yield using P–(CH\(_2\))\(_2\)–GeEt\(_2\)H (99). The polymer-supported organogermanium hydrides were used several times and recycled, and their efficiency was only reduced to 90% when compared with the first run.
2. Germanium-based linkers for solid-phase synthesis

The solid-phase synthesis of organic compounds requires a linkage element which acts as a tether to the polymeric support. In a multi-step synthesis the linker must be stable towards all reaction conditions used, but should easily and quantitatively be cleaved to release the target molecule without any degradation of the latter.

Recently, organogermanium compounds were used as novel linkers for the immobilization of organic compounds on polymer supports\textsuperscript{207,208}. Monoaryltrialkyl germanium compounds display a high stability towards bases and nucleophiles, but the germanium–aryl bond is readily cleaved by a variety of electrophilic reagents. Though germanium compounds are relatively expensive, they are promising candidates for the traceless linkage strategy of aromatic products. Compared with their silicon-containing analogues, they offer the advantage of the germanium–aryl bond to be more easily cleaved than the aryl–silicon bond. In organotin compounds the tin–aryl bond is even more easily cleaved but, as mentioned before, the organogermanium compounds are less toxic.

In Scheme 51, an example for the immobilization of the germanium-based precursor 100 to Argogel\textsuperscript{TM} polymer is shown\textsuperscript{208}. The clean release of several biaryl compounds from the polymer 101 was achieved by electrophilic degermylation with various reagents (i–iv) (Scheme 51).

![Scheme 51](image)

SCHEME 51. Immobilization of 4-methoxybiphenyl to Argogel\textsuperscript{TM} and release of the products by electrophilic degermylation

A linkage strategy was used for the solid-phase synthesis of a range of 1,4-benzodiazepine derivatives\textsuperscript{207}. It was demonstrated that the germanium route is superior to the silicon route because numerous functional groups are tolerated and the demetallation using trifluoroacetic acid or bromine is easier for germanium compounds. In Scheme 52
SCHEME 52. Solid-phase synthetic strategy for 1,4-benzodiazepine derivatives using a germanium linker strategy: i) polymer support linkage, ii) solid-phase synthesis, iii) product release

the general synthetic strategy, which was used for the solid-phase synthesis of eight 1, 4-benzodiazepine derivatives, is shown.

3. Germanium-containing polyacetylenes

Organic and organometallic substituents linked to a polyacetylene backbone influence the physical and chemical properties of the organic polymer. To study the effects of organogermanium moieties, the germanium-containing polyacetylenes 102–106 were prepared and their properties investigated. The polymerization of the dipropargylgermanium compounds \( R_2\text{Ge}(\text{CH}_2\text{C}≡\text{CH})_2 \) (\( R = \text{Me}, \text{Ph} \)) as catalysed by MoCl\(_5\)- and WCl\(_6\)-based catalysts gave the polymers 102, which have a polyene structure.
with recurring germanium-containing heterocycles. The soluble polymers had a $\lambda_{\text{max}}$ value of 430 nm and a number-average molecular weight of $M_n = 1.2 \times 10^4$.

\[
\begin{align*}
(102) & \quad R = \text{Me, Ph} \\
(103) & \quad R = \text{Me, } R' = \text{Me}_3\text{Ge} \\
(104) & \quad R = \text{Ph, } R' = o-\text{Me}_3\text{GeC}_6\text{H}_4 \\
(105) & \quad R = \text{Ph, } R' = p-\text{Me}_3\text{GeC}_6\text{H}_4 \\
(106) & \quad R = \text{H, } R' = o-\text{Me}_3\text{GeC}_6\text{H}_4
\end{align*}
\]

The polymers 104 and 105 were prepared from the corresponding acetylenes with a TaCl$_5$-based cocatalyst. The weight-average molecular weights were higher than $M_w = 1 \times 10^6$ as determined by GPC. In contrast, unsubstituted phenylacetylene yielded only relatively low molecular weight polymers with number-average molecular weights of $M_n \approx 1 \times 10^4$. The yellow trimethylgermyl-containing polymers 104 and 105 are thermally stable up to temperatures of ca 400°C. Poly(1-phenyl-2-o- trimethylgermylphenyl)acetylene (104) shows two absorption maxima at $\lambda_{\text{max}} = 380$ nm and 440 nm in the UV-visible spectrum and has an oxygen permeability coefficient which is about twice as high as that of poly(dimethylsiloxane). In contrast to its $p$-substituted analogue 105, the former polymer is also soluble in non-polar solvents. The structurally similar polymer 106 is also soluble in common organic solvents but differs significantly in its properties from 104 and 105. The dark purple solid ($\lambda_{\text{max}} = 551$ nm) has an onset temperature of weight loss at 230°C (TGA) and its oxygen permeability coefficient is ten times lower than that of 104.

**IV. COORDINATION POLYMERS OF ORGANOTIN AND ORGANOLEAD COMPOUNDS**

### A. Organotin Polymers

The high Lewis acidity of organotin derivatives having electron-withdrawing substituents bound to tin often results in a donor–acceptor complex formation with Lewis basic functionalities. To date, far more than 1000 crystal structure analyses of monomeric intra- and intermolecular coordinated compounds have been reported and even more complexes have been studied in solution. In addition, more than 300 oligomeric and polymeric organotin compounds have been studied by X-ray crystal structure analysis. In this Section, progress in the chemistry of tin-based coordination polymers covering the literature between 1995 and 2000 is reported, but selected results reported earlier and which we believe to be valuable for a better understanding of the matter are also included. The formation of oligomeric or polymeric organotin compounds can be achieved by the choice of suitable bidentate, tridentate or multidentate ligands. The coordination number at tin is increased to five or six resulting in tin-containing chain structures, layered compounds or three-dimensional networks. To date, the highest nuclearity observed in oligomeric organotin compounds is twelve. Several derivatives of the isostructural fragment $[(\text{RSn})_{12}(\mu_3-O)_{14}(\mu-OH)_6]^{2+}$ ($R = n$-Bu, $i$-Pr, $\text{Me}_3\text{SiCH}_2$) (107)
have been reported\textsuperscript{215–224}. A similar structural motif was observed in the cation \(([i-PrSn]_{12}(O)_{4}(OH)_{24})^{4+}\), which additionally encapsulates a Na\textsuperscript{+} ion in the organotin oxide core\textsuperscript{225}. The novel cluster \(([\text{Sn(CH}_{2})_{3}\text{Sn}]_{6}(\text{ClCH}_{2}\text{CO}_{2})_{14}(\text{OH})_{2}\text{O}_{10})\)\textsuperscript{226} was prepared starting from Cl\textsubscript{3}Sn(CH\textsubscript{2})\textsubscript{3}SnCl\textsubscript{3} and Cl\textsubscript{3}CH\textsubscript{2}COOH under the influence of air moisture.

\begin{equation}
\text{(107)} \quad \left[\text{(RSn)}_{12}\text{O}_{14}(\text{OH})_{6}\right]^{2+}
\end{equation}

\text{R} = n\text{-Bu, } i\text{-Pr, CH}_{2}\text{SiMe}_{3}

Only one diorganotin-based supramolecular compound with twelve tin atoms, namely \([\text{Me}_{3}\text{SiCH}_{2}(\text{Cl})\text{Sn(CH}_{2})_{3}\text{Sn(Cl)}(\text{CH}_{2})_{3}\text{Sn(Cl)}\text{CH}_{2}\text{SiMe}_{3}]\text{O}_{1.5}\)\textsuperscript{4} (108)\textsuperscript{227}, has been reported so far. The structure consists of three almost planar Sn\textsubscript{4}Cl\textsubscript{4}O\textsubscript{2} layers. Each layer is connected to the next layer by four trimethylene chains to give a triple ladder structure.

\begin{equation}
\text{(108)} \quad \text{R} = \text{CH}_{2}\text{SiMe}_{3}
\end{equation}

1. \textit{Intermolecular organotin–halide coordination}

Organotin fluorides\textsuperscript{214,228} show a strong tendency to associate in the solid state, unless bulky organic ligands or intramolecular donor coordination precludes the intermolecular
association. Examples of monomeric triorganotin fluorides 109a are the sterically overcrowded compounds Sn[C(SiMe2Ph)3]Me2F and Sn[C(SiMe3)3]Ph2F219, and the intramolecularly coordinated N(CH2CH2CH2)3SnF230 and [Me2N(CH2)3]2SnF2231. In polymeric chains of triorganotin fluorides, the tin atom is five-coordinate and has a trigonal bipyramidal configuration with the fluorine atoms in axial positions.

A symmetrical linear structure 109b with two identical Sn–F distances of 2.146(1) Å was reported for Ph3SnF232. In contrast, an unsymmetrical structure 109c with Sn–F distances of 2.051(10) Å and 2.303(10) Å was reported for the polymeric tricyclohexyltin fluoride233. For comparison, the Sn–F single bond distance in monomeric Sn[C(SiMe3)3]Ph2F amounts to 1.965(2) Å229.

\[ \text{monomeric} \quad \overset{\text{polymeric, linear}}{\text{polymeric, bent}} \]

\[
\begin{align*}
\text{(109a)} & \quad \text{X} = \text{F, Cl} & \text{(109b)} & \text{(109c)}
\end{align*}
\]

A particular behaviour was observed for the unsymmetrically substituted triorganotin fluoride Me2PhSnF234. In the solid state the tin fluoride adopts a 109c-type structure with only slightly different Sn–F distances of 2.162(1) and 2.179(1) Å, and Sn–F–Sn and F–Sn–F angles of 172.6(1) and 179.4(1)°, respectively. Depending on the concentration, the solvent and the temperature, in solution oligomers (Me2PhSnF)\(n\) up to an association degree of \(n = 50\) were observed. In addition, electrospray mass spectrometry proved the existence of species \([\text{Me2PhSn})_n\text{F}_{n-1}]^+\) with \(n = 1–5\).

Although Sn–Cl–Sn bridges are weaker than Sn–F–Sn bridges, they are strong enough to give self-organised polymeric organotin chlorides in the solid state83,214. A recent example of a triorganotin chloride crystallizing as a linear chain polymer of type 109b is tribenzyltin chloride, (PhCH2)3SnCl235, in which one short Sn–Cl distance of 2.387(2) Å and one long Sn–Cl distance of 3.531(2) Å were observed. In contrast, trimethyltin chloride236 forms a zigzag chain of type 109c, with Sn–Cl distances of 2.430(2) and 2.692(2) Å, and an Sn–Cl–Sn angle of 150.5°, whereas Ph3SnCl237 does not associate in the solid state and consists of discrete tetrahedral molecules of type 109a. Recently, the isostructural palladium and platinum complexes, \{MCl2[Ph2CH2CH2SnClMe2]3\}\(n\) (M = Pd, Pt) \(\text{(110, 111)}\)238, containing both organotin chloride and phosphine moieties, were reported. In the solid state the tin atoms adopt a distorted trigonal–bipyramidal configuration (110). Short intramolecular Sn–Cl distances in the range of 2.440(2)–2.679(2) Å (Pd) and 2.436(2)–2.682(2) Å (Pt), respectively, are accompanied by intermolecular Sn–Cl distances of 3.232(2)/3.234(2) Å (Pd) and 3.248(2)/3.223(3) Å (Pt), giving rise to formation of an infinite chain polymer. Both compounds were found to be monomeric in solution and, on the basis of heteronuclear NMR experiments, structure 111 was postulated.

The spacer-bridged ditin compound MeCl2Sn(CH2)3SnCl2Me239 was reported to contain, in the solid state, hexacoordinated tin atoms as a result of strongly unsymmetrical intermolecular Sn–Cl–Sn bridges with Sn–Cl distances in the range of 2.381(1)–3.484(1) Å, giving rise to the formation of a sheet-like polymer.
A two-dimensional sheet-like polymer was also observed in the solid state for the chloride complex \( \{ \text{Cl}_2\text{Sn}[(\text{CH}_2)_3\text{Sn}\text{Cl}_2\text{Me}]_2\}\text{Cl}^-\ [\text{Cl}_3\text{P}_2\text{N}]^{2-} \). As a result of the chloride complexation as well as of unsymmetrical intermolecular Sn–Cl–Sn bridges, the compound contains both penta- and hexacoordinated tin atoms. The dimethylene-bridged triorganotin bromide (Ph\(_2\)BrSnCH\(_2\))\(_2\)\(^{240}\) and the methylene- and dimethylene-bridged diorganotin dibromides (PhBr\(_2\)Sn\(_2\)(CH\(_2\))\(_2\)\(^{241}\) and (PhBr\(_2\)Sn\(_2\)(CH\(_2\))\(_2\)\(^{242}\), respectively, are rare examples for coordination polymers realised by unsymmetrical intermolecular Sn–Br–Sn bridges with Sn–Br distances in the range of 2.483–3.724(2) Å. An early example of this type of coordination polymers is Et\(_2\)SnBr\(_2\)\(^{243}\), which forms a polymer chain with tin atoms in a distorted octahedral coordination environment. The Sn–Br distances were found to be 2.505(4) and 3.777(4) Å.

A recent attempt to prepare an organotantalum fluoride starting from Me\(_3\)SiCH\(_2\)TaCl\(_4\) and excess Me\(_3\)SnF afforded the crystalline compound (Me\(_3\)SnCl·Me\(_3\)SnF·TaF\(_5\))\(_n\)\(^{113}\) containing octahedrally configurated tantalum and trigonal bipyramidally configurated tin atoms. The linear chain in \(^{113}\) was reported to consist of the unit [Sn–Cl–Sn–F–Ta–F–] with Sn–Cl distances of 2.555(3) and 2.562(2) Å and Sn–F distances of 2.514(7) and 2.54(9) Å. In addition, weak Sn–F contacts of 3.59(3) Å link the chains to give a two-dimensional layer.
22. Organometallic polymers of germanium, tin and lead

Long tin–fluorine interatomic distances, which are only slightly shorter than the tin–fluorine van der Waals distance of 3.64 Å, were reported for 1,4-[Me3SnOC-(CF3)2]2C6F4245. Fluorine atoms of both the CF3 and C6F4 groups are involved in intermolecular Sn–F interactions [3.462(11), 3.442(10) Å] giving rise to formation of a sheet-like polymer. This example illustrates that even very weak such interactions can be structure-directing in organotin chemistry.

Recently, a layered structure was reported for [(Me3Sn)3O]Cl (114)246. The oxonium salt was prepared by simply heating at reflux (Me3Sn)2O and Me3SnCl in THF (equation 1).

\[
\text{(Me}_3\text{Sn)}_2\text{O} + \text{Me}_3\text{SnCl} \xrightarrow{\text{thf, reflux}} \left[\text{(Me}_3\text{Sn)}_3\text{O}\right]\text{Cl}
\]

In the crystal lattice, the oxonium ion is trigonal planar coordinated by three Me3Sn groups. The two-dimensional structure is built up by a hexagonal AB layer with interlayer distances of 6.32 Å. Each hexagon consists of 12-membered Sn6Cl3O3 rings.

The single crystal X-ray structure analysis of the trimethyltin-substituted ammonium salt [H2N(SnMe3)2][SnMe3Cl2] (115)247 was also reported. In compound 115 the anion
[SnMe_3Cl_2]^- forms a trigonal bipyramid with the chlorine atoms in the axial positions. In the crystal lattice a chain structure is formed as the result of weak interionic tin–chlorine interactions [Sn···Cl 3.223(3), 3.182(3) Å] bridging the chlorine atoms of the anion and the tin atoms of the cation [H_2N(SnMe_3)_2]^+.

2. Intermolecular organotin–oxygen coordination

i. Intermolecular Sn–OR (R = H, alkyl) interactions. Usually, organotin hydroxides are associated by strong intermolecular tin–oxygen bonds and divers oligomeric and polymeric structures are known. The triorganotin hydroxides Et_3SnOH (116), Ph_3SnOH (117), BzMe_2SnOH (118) and Me_2Si(CH_2SnMe_2OH) (119) were fully characterised. They crystallise in a zigzag chain structure with the tin atoms being pentacoordinated. The hydroxide groups are located in the axial positions and the structures are bent at the oxygen. The Sn–O–Sn bridges are slightly unsymmetrical with Sn–O distances ranging from 2.15 to 2.29 Å. In contrast, the sterically overcrowded trimesityl tin hydroxide is monomeric in the solid state and the tin–oxygen bond length amounts to 1.999(6) Å.

Simple organotin alkoxides as well as the cyclic dioxaostannolanes are also suggested to associate in solution and in the solid state. The degree of association depends on
22. Organometallic polymers of germanium, tin and lead

both the steric requirements of the alkyl groups bound to tin as well as on the alkoxy groups. Trimethyltin methoxide, Me₃SnOMe (120)²⁵³, forms polymeric zigzag chains similar to Et₃SnOH (116) with the Sn—O—Sn bridge being again slightly unsymmetrical [Sn—O 2.20(2)/2.26(2) Å]. In dioxastannolane derivatives, relatively weak intermolecular tin–oxygen interactions were observed in the solid state and, for example, 2,2-di-n-butyl-1,3,2-dioxastannolane (121)²⁵⁴ forms a ribbon-type polymer with six-coordinate tin in a highly distorted octahedral arrangement. The intra- and intermolecular Sn—O bond lengths within the central Sn₂O₄ ring amount to 2.04(1) and 2.51(1) Å, respectively. The degree of association decreases in the sterically more crowded 2,2-di-t-butyl-1,3,2-dioxastannolane (122)²⁵⁵, for which dimers with pentacoordinated tin atoms were observed both in the solid state and in solution. The crystal structure analysis of 122 revealed two similar but structurally independent molecules with Sn—O bond lengths of 2.049(6)–2.253(7) Å.

\[ \text{polymer} \]

\[ \text{dimer} \]

(121) \( R = n\text{-Bu} \)

(122) \( R = t\text{-Bu} \)

The solution- and solid-state coordination behaviour of \( \omega \)-trichlorostannyl alcohols Cl₃Sn(CH₂)ₙOH (\( n = 3–5 \))²⁵⁶ were investigated by means of multinuclear NMR spectroscopy and, in the case of \( n = 5 \), by single crystal X-ray structure analysis. The latter revealed a polymeric structure for Cl₃Sn(CH₂)₅OH, which results from significant intermolecular HO—Sn interactions of 2.356(6) Å. The five-coordinate tin atoms exist in a distorted trigonal–bipyramidal geometry with the oxygen and one of the chlorine atoms occupying the axial positions (123a). It was suggested that Cl₃Sn(CH₂)₃OH and Cl₃Sn(CH₂)₄OH do not show intermolecular but intramolecular OH—Sn coordination, to give five- and six-membered rings (123b), respectively, both in CD₂Cl₂ solution and in the solid state.

\[ \text{(123a)} \]

\[ \text{(123b)} \]

*ii. Organotin carboxylates.* Organotin carboxylates have been the subject of numerous investigations and more than 300 X-ray crystal structure analyses have been reported to date²⁵⁷. The structural chemistry of organotin carboxylates was thoroughly reviewed by Tiekink²⁵⁸. In this section we focus on some representative examples of polymeric organotin carboxylates.
The tin–oxygen interatomic distances present in organotin carboxylates were classified in terms of primary Sn–O covalent bonds (ca. 2.0 Å), slightly longer dative Sn–O bonds (ca. 2.2–2.3 Å) and Sn···O secondary interactions (>2.5 Å).214 Triorganotin carboxylates can adopt the three idealised structure types 124a–c.

In 124a, the carboxylate is essentially monodentate resulting in tetrahedrally configured tin atoms. In 124b, the carboxylate is intramolecularly bidentate giving rise to a distorted trigonal–bipyramidal coordination geometry at tin with one oxygen and one carbon atom in the axial positions. In 124c, a linear polymer is formed as a result of unsymmetrically bridging carboxylate groups connecting trigonal bipyramidally configured tin centres. No example for the ideal structure 124a has been reported so far, since at least weak secondary interactions can be discussed in the molecular structures of triorganotin carboxylates.258 Structure 124b was only observed with aromatic carboxylic acids or with bulky substituents at tin. Recent examples are the triphenyltin derivatives of p-ethoxybenzoic acid, acetylsalicylic acid and phthalic acid.259 In the solid state, the structures of most of the triorganotin carboxylates approximate to the infinite chain polymer of type 124c in which the oxygen atoms occupy the axial positions of the trigonal bipyramid.258,260–271 The carboxylate groups not only bridge two tin centres, but in many structures an additional secondary intramolecular tin–oxygen interaction of approximately 3.0 Å was observed resulting in distortions of the trigonal–bipyramidal geometries. Very often, this effect was neglected in the discussion of crystal structure determinations. On the basis of the crystal structure analyses of seventeen polymeric triorganotin carboxylates, it was demonstrated that the tin–tin repeat distance in the polymers was approximately constant at 5.19 ± 0.21 Å, regardless of both the identity of the substituents at the carboxylic acids and the substituents at tin.261 A similar tin–tin repeat distance of 5.155 Å was reported for the polymeric diorganotin compound diethyl[3-(2-pyridyl)-2-sulfanylpropenato]tin, [Et₂Sn(pyspa)] (H₂pyspa = HOOC–C(SH)=CH–2-pyridine), which adopts a zigzag chain polymer structure similar to that of type 124c.

The crystal structure analyses of tin-containing dicarboxylates were also reported. Depending on the carboxylates used, linear infinite chain structures, two-dimensional, supramolecular layered structures and three-dimensional networks were observed. A chain polymer was reported for methylphenylammonium tributyl(pyridine-2,6-dicarboxylato)stannate (125), in which the tributyltin moieties are linked via the pyridine-2,6-dicarboxylate. The carboxylate groups form hydrogen bonds to the ammonium salt and thus no additional C=O···Sn interaction was observed. The coordination geometry at tin is again trigonal–bipyramidal with the oxygens in the axial positions [Sn–O 2.275(2), 2.279(2) Å].
Poly\[trans\]-bis(trimethyltin)-2,2'-bipyridyl-4,4'-dicarboxylate, Me$_3$SnOOC(2,2'-bipy)-COOSnMe$_3$ (126), forms a two-dimensional polymer. Each carboxylate group binds two trimethyltin moieties in a bridging bidentate fashion giving a layered structure. The tin atoms show a slightly distorted trigonal–bipyramidal configuration with two essentially different axial Sn−O bond lengths of 2.145(2) and 2.519(2) Å.

Bis(trimethyltin)malonate, Me$_3$SnOOCCH$_2$COOSnMe$_3$ (127), is an intriguing example of a three-dimensional network built up by pentacoordinated organotin moieties with the oxygens in the axial positions of a trigonal bipyramid [Sn−O 2.19(1), 2.17(1), 2.44(2), 2.46(2) Å] and malonate units as tetradentate spacers. The basic three-dimensional structure consists of four helices which are interconnected by O−Sn−O bridges resulting in 24-membered macrocycles.

A donor atom-containing substituent in the alkyl or aryl group R' in carboxylic esters of the type R'COOSnR$_3$ makes possible an alternative bonding to carboxylate bridging. A range of substituted carboxylic acids having an additional donor group was reported to give polymeric triorganotin compounds in the solid state. Among the earliest examples
was trimethyltin glycinate (128)\textsuperscript{279} whose X-ray single crystal structure analysis revealed a polymeric network as a result of tin–nitrogen interactions with Sn–N bond lengths of 2.46(2) Å. In addition, the carboxylate group is involved in O···H–N hydrogen bonding. A more recent example for a triorganotin ester with additional Sn–N linkage is triphenyltin-3-pyridylcarboxylate [Sn–N 2.568(7) Å] (129)\textsuperscript{280}.

Mössbauer and infrared spectroscopic data in the solid state of tributyltin 2-benzoylbenzoate (130a) and triphenyltin 2-benzoylbenzoate (130b) were indicative for
a trans-$\text{C}_3\text{SnO}_2$ trigonal–bipyramidal geometry at tin. A single crystal X-ray structure analysis confirmed this assumption and revealed a polymeric chain structure as a result of ketonic oxygen–tin bridges for both compounds. The tin–ketonic oxygen distances in 130a and 130b amount to 2.675(10) Å and 2.880(4) Å, respectively. Analogously, triphenyltin derivatives of pyridylcarboxylic acid N-oxides crystallise as N-oxide bridged chains with pentacoordinated tin atoms and monodentate carboxylate groups.

The solid state structures of heteroatom-substituted carboxylic triorganotin esters are difficult to predict. In some cases the heteroatom indeed functions as a bridge between the tin centres, but often the polymeric nature of the compound results from bidentate carboxylate ligands giving the general trans-$\text{R}_3\text{SnO}_2$ structure-type. For example, in 130 the heteroatom represents the linking functionality, whereas in catena-poly[trimethyltin-µ-(3-benzoyl-α-methylbenzeneacetato-O1,O1)] and dithiocarbamoylacetato-triphenyltin derivatives, the heteroatoms are not involved in coordinative bonds to tin.
The synthesis and characterization of a series of triphenyltin derivatives of \(N\)-2-hydroxynaphthylidene-\(\omega\)-amino acids, 2-HOC\(_{10}H_6\)CH=NC\((CH_2)\)\(n\)COOH, and \(n\)-salicylidene-\(\omega\)-amino acids, 2-HOC\(_6\)H\(_4\)CH=NC\((CH_2)\)\(n\)COOH (\(n = 1, 2, 3\) and 5)\(^{285}\), were reported. The X-ray crystal structure analysis of 2-HOC\(_6\)H\(_4\)CH=NC\((CH_2)\)\(5\)COOSnPh\(_3\) (133) showed the phenolic hydroxyl groups to be involved in the O(H)–Sn coordination with a Sn–O bond length of 2.328(4) Å. The tin atom is five-coordinate with the phenolic oxygen and one oxygen of the carboxylic group [Sn–O 2.148(4) Å] in the axial positions of a trigonal bipyramid. In addition, a weak Sn–O interaction [Sn–O 2.973(5) Å] involving the second oxygen of the carboxylic group causing a distortion of the trigonal bipyramid was observed. It was suggested that the other compounds of the series have a similar structural arrangement.

![Chemical structure of 133](image)

By appropriate choice of the reactants and the reaction conditions, a phenol-substituted carboxylic acid may react with an organotin compound to give both an organotin ester and an organotin aryl oxide within the same molecule. The reaction of trimethyltin chloride with 4-hydroxy-3-methoxybenzoic acid (HVAH) in the presence of water and pyridine at 130°C in a sealed tube gave the unique two-dimensional coordination polymer 134 (equation 2)\(^{286}\).

\[
\text{HO} \text{COOH} + \text{Me}_3\text{SnCl} \xrightarrow{\text{pyridine/H}_2\text{O}} \left\{[(\text{Me}_2\text{Sn(VA)}_{0.5})_2\text{O}]_2 \text{2H}_2\text{O}\right\}_n
\]

The molecular structure of 134 exhibits a two-dimensional rhombohedral grid\(^{286}\) in which the corners are composed of a ladder-type arrangement which is typical for tetraorganodistannoxanes\(^{258,287}\). The endocyclic tin atoms of the basic ladder fragment are connected by two oxygens to give the central almost planar Sn\(_2\)O\(_2\) ring. Each tin atom has a trigonal–bipyramidal geometry. The axial positions are occupied by an oxygen of a phenolato group and an oxygen of a carboxylate from different VA\(^{2-}\) moieties. Thus, each VA\(^{2-}\) ligand uses one phenolate oxygen and one carboxylate oxygen to function as a spacer connecting the ladders, to give a two-dimensional rhombic grid. Two water molecules are located in the rhombic cavity of 134 as a result of hydrogen bonds between water and a carboxylate group. In addition, the two water molecules form hydrogen bonds between each other.

One-dimensional polymeric tetraorganodistannoxanes based on a typical ladder arrangement \(L_4R_8\text{Sn}_4\text{O}_2\) (\(L = \text{ligand, e.g. halogen, carboxylate; R = alkyl, aryl}\) were
reported, but their polymeric structures are quite different from that of 134. In $\text{Me}_2\text{Sn(OOCMe)}_2\text{O}_2$ (135) a polymeric chain of the basic ladder structure entity results from an intermolecular interaction of an exocyclic tin atom and an oxygen of a monodentate carboxylate group [Sn–O 2.56(1) Å]. The covalent Sn–O bond length of the monodentate carboxylate amounts to 2.26(1) Å with an additional weak intramolecular tin-oxygen interaction of 2.89(1) Å.

A quite different bonding situation was observed in the crystal structure of bis{dimethyl[trans-3-(2-thiophenyl)-2-propenato]tin}oxide $\text{Me}_2\text{Sn(OOC\text{=CHC}_4\text{H}_3\text{-S})}_2\text{O}_2$ (136), in which two additional weak intermolecular interactions of carboxylate oxygens of two monodentate carboxylate groups to adjacent tins (Sn–O 2.953 Å) result in a one-dimensional coordination polymer. In addition, the same carboxylate oxygen chelates the tin atom to which the ligand is bound (Sn–O 2.850 Å).

Different synthetic routes were developed to prepare distannoxane carboxylates. Two methods commonly used are (i) the reaction of diorganotin oxides with carboxylic acids under azeotropic removal of water and (ii) the hydrolysis of diorganotin dicarboxylates. Diorganotin dicarboxylates are highly moisture-sensitive.
and the few compounds which are structurally characterised show diverse structure types. Dimethyltin diacetate, $\text{Me}_2\text{Sn(OOCMe)}_2$\textsuperscript{290}, is monomeric, di-$n$-butyl(1,1-cyclobutanedicarboxylato)tin, [\(n\)-Bu\(n\)-Bu\(n\)-Sn(OOC\(n\)-C\(_6\)H\(_6\)COO)]\(_n\)\textsuperscript{291}, is a one-dimensional polymer with a zigzag chain, bis(formato)dimethyltin, [\(\text{Me}_2\text{Sn(OOCH)}_2\)]\(_n\)\textsuperscript{292}, is a sheet-like polymer with linear Me\(_2\)Sn moieties nearly symmetrically bridged by formate anions and bis(trifluoroacetato)dimethyltin, [\(\text{Me}_2\text{Sn(OOCFCF}_3\)]\(_n\)\textsuperscript{290}, crystallises in a three-dimensional network formed by bridging trifluoroacetate groups around octahedrally coordinated tin atoms.

The behaviour in solution of dimethyltin(IV) complexes containing different aminopolycarboxylic acids were also investigated\textsuperscript{293,294}. The X-ray crystal structure analyses of the tin complexes with \(N\)-methyliminodiacetate (mida), pyridine-2,6-dicarboxylate (pdc) and ethylenediamine-$N,N'$-diacetate (edda) revealed dimeric structures for the first two compounds and a monomeric structure for the complex dimethyltin (edda). In contrast, the dimethyltin(IV) complex (137) with ethylenediamine-$N,N,N',N'$-tetraacetate (edta) and water is a polymer in which each tin atom adopts a distorted pentagonal–bipyramidal configuration with the two methyl groups in axial positions.

\(\text{Sn} \rightarrow \text{O(ketone)}\) interactions. 1,4-dimethylpiperazine-2,5-dione is the simplest cyclic peptide, which was used to study adducts with SnCl\(_4\), BuSnCl\(_3\), Me\(_2\)SnCl\(_2\) and Ph\(_2\)SnCl\(_2\) by \(^{119}\)Sn Mössbauer and IR spectroscopy\textsuperscript{295}. The crystal structure analysis of the 1:1 complex of Ph\(_2\)SnCl\(_2\) and 1,4-dimethylpiperazine-2,5-dione (138) revealed an infinite polymeric zigzag chain, in which the octahedrally coordinated tin atoms are
bridged by ketonic oxygen atoms \( [Sn-O 2.379(6), 2.468(6) \text{ Å}] \). The phenyl groups are in mutual \textit{trans} position and both the chlorine atoms as well as the oxygens are \textit{cis}.

Both the \( N\)-mono- and \( N,N\)-bis(trimethylstannyl)acetamides, \( \text{MeC(O)NMe(SnMe}_3) \) \((139a)\) and \( \text{MeC(O)N(SnMe}_3)_2 \) \((139b)\) form polymeric chain-like arrays with pentacoordinated tin atoms in the solid state.\(^{296}\) In \(139a\) and \(139b\) the intermolecular \(Sn-O\) distances amount to \(2.564(4) \text{ Å}\) and \(2.672(3) \text{ Å}\), respectively and the \(Sn-N\) distances to \(2.173(3) \text{ Å}(139a)\) and \(2.098(3)/2.155(3) \text{ Å}(139b)\). A similar structure was also reported for \(N\)-(trimethylstannyl)-\(N\)-nitromethylamine, \(\text{Me}_3\text{SnN(Me)NO}_2\) \(^{297}\), which is build up by infinite \(\text{SnMe}_3-N(\text{Me})-N(\text{O})-O-\)chains. The oxygen and the nitrogen atoms occupy the axial positions in the trigonal bipyramid with \(Sn-O\) and \(Sn-N\) distances of \(2.39(5)\) and \(2.33(4) \text{ Å}\), respectively.

![Structure](image)

\((139a)\) \(R = \text{Me}\)
\((139b)\) \(R = \text{SnMe}_3\)

iv. \textit{Intermolecular Sn–O=S and Sn–O=Se interactions}. Organotin compounds with intermolecular \(Sn-O=S\) or \(Sn-O=Se\) interactions are relatively rare and only a few single crystal X-ray structure analyses have been reported. Early examples of coordination polymers are the trimethyltin sulphinates \(\text{Me}_3\text{SnO}_2\text{SR} (R = \text{Me}, \text{CH}_2\text{C≡CH})\)\(^{298–300}\) and the corresponding selenates \(\text{R}_3\text{SnO}_2\text{SeR} (R = \text{Me}, \text{Ph})\)\(^{301,302}\). The synthesis and solid state structure determination of the organotin selenite derivative \((\text{Me}_3\text{Sn})_2\text{O}_3\text{SeH}_2\text{O}\) \((140)\)\(^{303}\) was also reported. One of the tin atoms is part of a polymeric chain in which the tin centres are bridged by two oxygens of the tridentate ligand \([Sn-O 2.263(6), 2.293(6) \text{ Å}]\), while the second tin is pendant to the chain linked via the third oxygen of the \(\text{SeO}_3^{3–}\) group \([Sn-O 2.139(6) \text{ Å}]\). The latter tin atom is coordinated by a water molecule \([Sn-O 2.660(7) \text{ Å}]\), which itself forms hydrogen bonds to the selenite group. The overall structure is that of a three-dimensional network composed of pentacoordinated tin atoms. A similar structure was reported for bis(triphenylstannyl)sulphite, \([\text{(Ph}_3\text{Sn})_2\text{O}_3\text{S}]_n\) \((141)\)\(^{304}\), which crystallised without water, with the consequence that \(141\) contains pentacoordinated tin atoms. In the case of the pentacoordinated tin atoms, the axial \(Sn-O\) bond lengths amount to \(2.264(3)\) and \(2.252(3) \text{ Å}\), which are significantly longer than the \(Sn-O\) bond length for the tetracoordinated tin \([Sn-O 2.032(2) \text{ Å}]\).

A two-dimensional polymeric sheet-like structure was reported for \(\text{Me}_2\text{Sn(SO}_3\text{F)}_2\) \(^{305}\) and a polymeric zigzag chain for chlorotris(\(p\)-methylsulphonylphenyl)tin, \([\text{SnCl(C}_6\text{H}_4-\text{SO}_2\text{CH}_3-p)]_n\) \((142)\)\(^{306}\). In \(142\), the tin atoms are pentacoordinated as a result of a weak intermolecular \(Sn-O\) interaction of \(3.046(5) \text{ Å}\). Only one out of the three \(p\)-methyl-sulphonylphenyl groups is involved in coordinative oxygen–tin bonds.
Similar to the structure of compound 142, trigonal–bipyramidal tin centres with weak sulphoxide oxygen–tin interactions were observed in the polymeric chain structures of compounds 143–146\(^{307,308}\). The Sn–O lengths were reported to be in the range of 2.82 to 3.14 Å.

In diorganotin dihalide complexes with sulphoxide-containing ligands, the coordination number at tin is increased to six and the sulphoxide oxygen–tin distances are significantly shortened as compared with 142–145. In poly[cis-dichloro-trans-dimethyltin-\(\mu\)-meso-1,2-bis(phenylsulphinyl)ethane-O:O\] (146a) and poly[cis-dichloro-trans-dimethyltin-\(\mu\)-meso-1,2-bis(propylsulphinyl)ethane-O:O\] (146b), Sn–O distances of 2.397(3) and 2.404(3) Å, and 2.316(3) and 2.320(3) Å, respectively, were observed\(^{309,310}\). The disulphoxide ligands bridge the hexacoordinated tin centres to give infinite chains in the solid state.
(143)

(144)

(146a) R = Ph

(146b) R = Pr
v. Intermolecular Sn–O=P interactions. Attempts to prepare organotin derivatives of phosphorus acids usually resulted in amorphous powders unsuitable for X-ray diffraction. However, the crystal structure analysis of one representative, namely (Me₂Sn)₃(PO₄)₂·8H₂O, was reported. The organotin phosphate is build up by fused eight-membered Sn₂O₄P₂ rings with alternating Me₂Sn and PO₄ groups leading to infinite ribbons. Coordination of water molecules to tin and extensive hydrogen bonding results in a complex three-dimensional network. Organotin derivatives of organophosphorus acids show a higher solubility and a series of complex oligomeric structures including drums, cubes, oxygen-capped clusters, butterfly formations, crowns and polymers were characterised by X-ray crystallography. These compounds were prepared by (i) azeotropic dehydration of a mixture of an organotin hydroxide or organotin oxide, respectively, and the acid, (ii) by salt elimination from an organotin halide and the salt of the phosphorus-containing acid, or (iii) by treating a tin alkoxide or tin amide with the corresponding acid. Based on NMR and ¹¹⁹Sn Mössbauer spectroscopic investigations it was concluded that tributyltin phosphate, (Bu₃SnO)₃P(O), tributyltin phenylphosphonate, (Bu₃SnO)₂P(O)Ph, and tributyltin diphenylphosphinate, Bu₃SnO₂PPh₂, are intermolecularly associated through the O=P=O group both in solution and in the solid state. In contrast, dithiophosphorus acid derivatives show a higher tendency to function as chelating rather than bridging ligands.

The triorganotin phosphinates Me₃SnO₂PMe₂ (147a), Me₃SnO₂PCl₂ (147b) and Bu₃SnO₂PPh₂ (147c) self-assemble in the solid state to give polymeric helical chain structures with pentacoordinated tin and tetracoordinated phosphorus atoms. The Sn–O distances in 147a, 147b and 147c amount to 2.20(1), 2.265(5) and 2.220(6)/2.224(6) Å, respectively, and the P–O distances are in the range of 1.45–1.50 Å.

In contrast to the solid state, the molecular weight determination of tributyltin diphenylphosphinate, Bu₃SnO₂PPh₂, in benzene indicated a dimeric structure in solution at low concentration. Other triorganotin phosphinates, such as Me₃SnO₂PPh₂ (148) and Ph₃SnO₂P(OPh)₂, crystallise as cyclic tetramers and hexamers, respectively.

Some diorganotin derivatives of phosphinic acids were reported to self-assemble in the solid state to give polymeric arrays. In [Et₂ClSnO₂PMe₂]ₙ, the O₂PMe₂ groups act as bidentate bridging ligands between the Et₂ClSn units leading to a polymeric chain structure. The tin atoms exhibit a distorted trigonal–bipyramidal geometry with the oxygen atoms in the axial positions. A peculiarity of the structure is the formation of –P–O–Sn–O– double chains running in relatively close distance to...
each other in the direction of the $c$-axis of the unit cell. The two strands are held together by weak Sn−O interactions [Sn−O 3.162(4) Å], thereby causing a [5+2]-coordination geometry at tin.

In the polymeric diorganotin phosphinates $[\text{Et}_2\text{Sn}(\text{O}_2\text{PPh}_2)_2]_n$ (150a)$^{322}$ and $[\text{Ph}_2\text{Sn}(\text{O}_2\text{PMe}_2)_2]_n$ (150b)$^{323}$, the phosphinate groups function as double bridges between the octahedrally coordinated tin atoms to give centrosymmetric $(\text{SnOP})_2$ eight-membered rings. The Sn−O distances show values of 2.141(4)–2.182(4) Å (150a) and

(150a) $R^1=\text{Et}, R^2=\text{Ph}$

(150b) $R^1=\text{Ph}, R^2=\text{Me}$
2.210(4)–2.229(3) Å (150b). The organic groups are mutually trans and thus linear arrays of the (SnOPO)₂ rings are observed. The diorganotin phosphinate [Et₂Sn(O₂PMe₂)₂]ₙ (151) shows a similar coordination geometry at tin and bidentate bridging O₂PMe₂ groups were found. Somewhat unexpectedly, the diethyltin phosphinate crystallises in a layer structure containing 16-membered (SnOPO)₄ rings.

Among the organotin thiophosphinate derivatives known so far, polymeric chain structures were reported for [Ph₃Sn(OSSH₂)]ₙ, [Me₃Sn(OSPMe₂)]ₙ and [Me₂Sn(OSPPh₂)]ₙ.

Diphosphoryl ligands are able to function either as chelating or as bridging ligands in organotin halide complexes. Infinite chain structures were reported for complexes of diorganotin dichloride with 1,2-bis(diphenylphosphinyl)ethane [dppoe, Ph₂P(O)CH₂CH₂P(O)Ph₂], such as [Bu₂SnCl₂(dppoe)]ₙ and [PhBuSnCl₂(dppoe)]ₙ, as well as for the related complex of dimethyltin dichloride with meso-1,2-bis(α-diethoxyphosphorylbenzylamino)ethane, {Me₂SnCl₂[(EtO)₂P(O)CH₂CH₂CHMeP(O)-(OEt)₂]}ₙ (152) and the diphenyltin dichloride complex {Ph₂SnCl₂[(EtO)₂P(O)CH₂CH₂CHMeP(O)-(OEt)₂]}ₙ. In all complexes the tin atoms are hexacoordinated, but only in the latter are
the phosphoryl oxygens cis. The tin–oxygen distances are in the range of 2.24–2.64 Å, depending on both the steric and electronic properties of the ligands attached to phosphorus and tin.

An infinite chain polymer was also reported for \([\text{[Me}_2\text{Sn}((\text{MeSO}_2)_2\text{N})(\text{OH})]_2\text{dppoe}}]_n\) \((153)\), in which the tin atoms are heptacoordinated as a result of inter- and intramolecular Sn–O interactions.

![Diagram of (153)](image)

Several triorganotin carboxylates crystallise as chain polymers of type \(124c\) in which the carboxylate serves as a bridging ligand. In the one-dimensional polymer structures of triphenyltin diethylphosphonoacetate \((154a)\) \((154b)\), the carboxylates are monodentate and the linear polymeric arrays result from intermolecular phosphoryl oxygen–tin interactions with Sn–O bond lengths of 2.420(3) Å and 2.397(3) Å, respectively. As a result of the slightly different chain length of the CH \(_2\) spacers, the polymeric chains in the acetate \((154a)\) propagates by translation along the \(b\)-axis to give a linear arrangement, whereas in the propionate \((154b)\) the chain propagates along the \(c\)-axis to give a zigzag conformation.

\(3. \text{Intermolecular organotin–nitrogen coordination}\)

Trimethyltin cyanide, \(\text{Me}_3\text{SnCN}\), was among the first coordination polymers investigated with intermolecular tin–nitrogen interactions. The tin atoms are in a trigonal–bipyramidal environment with three equatorial methyl groups and equally distant cyanide groups in the axial positions giving rise to formation of a linear polymeric array of the type \(155a\). It was suggested that the structure ‘is best described as an arrangement
of $\text{Me}_3\text{Sn}^+$ and $\text{CN}^-$ ions with the cyanides ordered in the direction along an axis, but disordered in orientation along this axis, with perhaps a small amount of covalent character to account for the orientation of the CN groups. Triethyltin cyanide, $\text{Et}_3\text{SnCN}$, was reported to have a similar structure whereas trimethylcyanogermane, $\text{Me}_3\text{GeCN}$, does not associate in the solid state. Dimethylditin dicyanide, $\text{Me}_2\text{Sn}($CN$)_2$, forms infinite polymeric sheets as a result of intermolecular tin–nitrogen interactions of 2.641(11) Å. In $\text{Me}_2\text{Sn}($CN$)_2$, the tin atom has a strongly distorted octahedral environment as is illustrated by the C–Sn–C trans angles of 148.7(35)° for the $\text{Me}_2\text{Sn}$ moiety and the NC–Sn–CN cis angles of 85.3(37)° for the Sn($\text{CN})_2$ moiety. The coordination environment of the analogous germanium compound $\text{Me}_2\text{Ge}($CN$)_2$ is close to tetrahedral with C–Ge–C angles of 120.9(8)°, 109.5(5)° and 100.9(7)° for the $\text{Me}_2\text{Ge}$, Ge($\text{CN})_2$ and $\text{MeGeCN}$ moieties, respectively. However, intermolecular Ge–N distances of 3.28(2) Å indicate weak association.

Trimethyltin azide, $\text{Me}_3\text{SnN}_3$, is a one-dimensional zigzag polymer of the type $\text{155b}$ in which tin is trigonal–bipyramidally coordinated with the methyl groups in equatorial and the nitrogens in axial positions. The Sn–N distances are equal and amount to 2.386(3) Å, which is longer than the Sn–N distances in the monomeric t-$\text{Bu}_3\text{SnN}_3$ [Sn–N 2.101(4) Å] and t-$\text{Bu}_2\text{SnN}_3$ [Sn–N 2.156(3), 2.141(2) Å].

Bis(trimethyltin)carbodiimide, $\text{Me}_3\text{SnNCNSnMe}_3$, forms an infinite helical network similar to $\text{Me}_3\text{SnN}_3$, in which trigonal–bipyramidally coordinated tin atoms are linked via $\mu$-nitrogens of the NCN dianion. Both nitrogens of a NCN$^2$ ligand are part of different N–Sn–N–Sn chains, which results in the infinite network with tetradentate NCN$^2$ ligands (155c). $N$-Trimethylstannyl-$N'$-nitrocarbodiimide, $\text{Me}_3\text{Sn}[\text{NCN(NO}_2\text{)}]$341, is an example for a bidentate NCN-group which bridges two tin centers via the 1- and 3-position to give a polymeric chain structure of type 155d.

The crystal structure analysis of trimethyltin dicyanamide, $\text{Me}_3\text{Sn}[\text{N(CN)}_2]$, exhibits a similar structure as that reported for trimethyltin cyanide (155a) containing bipyramidal coordinated tin atoms which are connected by the ligand to give an infinite zigzag chain of the type 155e. The average Sn–N distance is 2.335(9) Å. In the diorganotin compound $\text{Me}_2\text{Sn}[\text{N(CN)}_2]_2$, the tin centres are octahedrally coordinated with the methyl groups mutually trans. Thus, a two-dimensional layer structure composed of fused 16-membered rings (156) is formed. The Sn–N distances of 2.289(6) Å are comparable with the corresponding distances reported for the trimethyltin analogue, $\text{Me}_3\text{Sn}[\text{N(CN)}_2]$.
4,4′-Bipyridine and pyrazine are potentially cross-linking \( N, N′ \)-bidentate ligands which are capable of metal coordination to give one-dimensional polymers. In organotin coordination chemistry, some structural investigations of such coordination polymers were reported\(^{343-346} \). Among these is the acetonitrile solvate of poly[(\( \mu \)-4,4′-bipyridine)trimethyltin]dimesylamide, \( \{ \text{Me}_3\text{Sn}[\text{N(SO}_2\text{Me})_2]\}_{n} \cdot 4,4′\text{-bipy} \) \(^{(157)} \), which forms infinite chains of \( \text{Me}_3\text{Sn}^+ \) cations bridged by 4,4′-bipyridine ligands\(^{345} \). The tin atoms are pentacoordinated and the anions (MeSO\(_2\))\(_2\)N\(^-\) as well as the CH\(_3\)CN molecules are non-coordinating. The Sn–N distances amount to 2.420(2) and 2.411(2) Å and the N–Sn–N angle is 176.8(1)°. In contrast to the coordination polymer \(^{(157)} \), organotin halides form neutral complexes with pyrazine without dissociation of the tin–halide bond.

The one-dimensional coordination polymer \(^{(158)} \) with hexacoordinated tin atoms resulted from the reaction of diphenyltin dibromide with bis(1,2,4-triazol-1-yl)methane\(^{347} \). The bis(triazol-1-yl)methane coordinates to the tin atom in a bidentate bridging fashion through the nitrogen atoms at the 4-position of the triazole rings with intermolecular Sn–N distances of 2.454(7) Å.
Various types of triorganotin compounds bound to nitrogen-containing heterocycles such as imidazole, triazole and tetrazole derivatives were also investigated. In particular, tetrazole derivatives may coordinate to tin in a variety of different bridging modes. One example for a structurally characterised coordination polymer is 2,2-diphenyl-1,7,8,9-tetraaza-2-stannabicyclo[4.3.0]nona-6,8-diene. The tin atom in this compound is pentacoordinated with the nitrogens in axial positions of a trigonal bipyramid. The intramolecular and intermolecular Sn–N bond lengths amount to 2.34(1) Å and 2.39(1) Å, respectively, and the N–Sn–N angle is 173.8(5)°.

A series of bis(triorganostannyl)tetrazoles of the type \((R_3SnN_4C)_2X\) \((X = (CH_2)_n, n = 1, 2, 4–6; 1,2-C_6H_4; 1,3-C_6H_4; 1,4-C_6H_4; R = Me, Et, i-Pr, n-Bu)\) and trifunctional triorganotin tetrazoles of the type \((R_3SnN_4CCH_2CH_2)\)3C(NO2) and \(1,3,5-(R_3SnN_4C)\)3C6H3 \((R = Me, Et, n-Bu)\) were synthesised and characterised by \(^1H\), \(^13C\), \(^{119}Sn\) NMR, \(^{119}Sn\) Mössbauer spectroscopy and single crystal X-ray structure analyses. The single crystal X-ray structure analyses of the coordination polymers revealed that (i) usually a trans-N2SnC3 environment at tin is observed, (ii) each tetrazole moiety acts as a bidentate bridging ligand and (iii) the intramolecular and intermolecular Sn–N distances are in the range of 2.24 to 2.56 Å. Depending on the identity of the tetrazole ligand and the organic groups attached to tin, different two- and three-dimensional structures were observed. It is noteworthy that \([(Et_3SnN_4C)\)2(1,2-C6H4)] \((160a)\) forms a two-dimensional coordination polymer, whereas the closely related \([(n-Bu_3SnN_4C)\)2(1,2-C6H4)] \((160b)\) forms a three-dimensional network.

Triorganotin cyanometallates. A fascinating class of mainly three-dimensional coordination polymers based on Sn–N interactions is accessible via the connection of cyanometallate ions and trialkyl or triaryl tin cations. The general formula of this class of compounds is \([R_3Sn)_M(CN)\]n \((R = alkyl, aryl; M = transition metal)\). These cyanometallates were described to adopt a variety of networks with different topologies. In general, all compounds contain the sequence \(M–C≡N–SnR_3–N≡C–M\), in which the tin atom is pentacoordinated with the nitrogens in the axial and the alkyl or aryl groups in the equatorial positions of a trigonal bipyramid. Some of these compounds have large cavities and, despite their usually low thermal stability with decomposition temperatures in the range from 250–350 °C, these compounds were suggested to be promising candidates for applications such as ion exchange, molecular sieves and heterogenous catalysis. The first structurally characterised example, namely \([(Me_3Sn)_3Co(CN)_6]\)n, has a framework
\[(\text{Sn})\text{N} - \text{N} - \text{N} - \text{N}\text{SnR}_3 \quad (\text{Sn})\text{N} - \text{N} - \text{N} - \text{N}\text{Bu}_3\text{Sn} \quad (\text{Sn})\text{N} - \text{N} - \text{N} - \text{N}\text{SnBu}_3\]

\[(\text{Sn})\text{N} - \text{N} - \text{N} - \text{N}\text{NO}_2 \quad \text{N} - \text{N} - \text{N} - \text{N}\text{SnBu}_3 \]

\[(\text{Sn})\text{N} - \text{N} - \text{N} - \text{N}\text{SnBu}_3 \quad \text{N} - \text{N} - \text{N} - \text{N}\text{SnBu}_3 \quad \text{N} - \text{N} - \text{N} - \text{N}\text{SnBu}_3 \]

\[(\text{SN})\text{N} - \text{N} - \text{N} - \text{N}\text{SnBu}_3 \quad \text{N} - \text{N} - \text{N} - \text{N}\text{SnBu}_3 \]

(160a) \(R = \text{Et}\) two-dimensional sheet
(160b) \(R = \text{Bu}\) three-dimensional array
(160c) bilayer
(160d) mono-layer
(160e) mono-layer
containing large channels\(^{362,363}\). The latter compound was prepared quantitatively by the reaction of Me\(_3\)SnCl with K\(_3\)[Co(CN)\(_6\)] in aqueous solution. The resulting cyanometallate [(Me\(_3\)Sn)\(_3\)]Co(CN)\(_6\)]\(_n\) is not isostructural with [(n-Bu\(_3\)Sn)\(_3\)]Co(CN)\(_6\)]\(_n\) (162)\(^{364}\), which demonstrates that slight modifications of the basic structural building units may result in different three-dimensional architectures. In compound 162 each Co(CN)\(_6\) octahedron is corner shared through Sn atoms with six neighbours and each Co atom is a vertex of three 18- and five 30-membered rings (−C≡N−Sn−N≡C−sequences). The 18-membered ring consists of three Co(CN)\(_6\) octahedra and three Bu\(_3\)Sn moieties.

Much work has been devoted to the preparation and characterization of hexacyanoferrate compounds of the type [(R\(_3\)Sn)\(_x\)]Fe(CN)\(_6\)]\(_n\) (x = 3, 4; R = alkyl, aryl)\(^{364−378}\). An interesting example in this series is [(Ph\(_3\)Sn)\(_3\)]Fe(CN)\(_6\)·H\(_2\)O·2CH\(_3\)CN]\(_n\) (163), in which one nitrogen of the Fe(CN)\(_6\)\(^{3−}\) unit is not coordinated to a triphenyltin moiety. This nitrogen atom is linked to a water molecule via hydrogen bonding [O−N 2.82(2) Å] and the water molecule is coordinated to a Ph\(_3\)Sn\(^+\) cation [Sn−O 2.34(1) Å]. The insertion of water into the framework structure is suggested to result from the steric requirements of the triphenyltin moiety. The average Sn−N distance in 163 is 2.33(1) Å, which is comparable to other values reported for this class of compounds. Channels which are occupied by phenyl groups and acetonitrile molecules were formed along the b axis in the crystal lattice of 163 as shown below.
22. Organometallic polymers of germanium, tin and lead

(163)-coordination environment

(163)-framework
A number of other transition metals including Ru and Os\textsuperscript{369,372,379}, Cu\textsuperscript{380–383}, Zn\textsuperscript{380}, Au, Pd and Pt\textsuperscript{384}, Ni\textsuperscript{385,386}, Mo and W\textsuperscript{387,388} were also used to prepare supramolecular self-assembled triorganotin cyanometallates. A detailed description of all these compounds is beyond the scope of this article and only the structures of two representatives are discussed in more detail. The copper-containing derivative \([\text{CuCN-Me}_3\text{SnCN-0.5 bipy}]_n\) (bipy = 4, 4′-bipyridine) \((164)\) forms planar sheets held together by almost perpendicular bipyridine pillars\textsuperscript{382}. The sheets consist of \([\text{Cu}_2(\mu-\text{CN})_2(\text{CN})_2]\) fragments which are connected via \(\text{CN-SnMe}_3-\text{NC}\) sequences with the nitrogens in the axial positions of a trigonal–bipyramidal configurated tin to give 24-membered rings. The bipyridine ligands, which connect the layers by bridging the copper atoms of different layers, are omitted for clarity. The crystal lattice consists of two equivalent, ideally interpenetrating frameworks in which each bipyridine pillar of one framework passes the centre of the 24-membered ring of the second framework. The second example of the above mentioned series is \([\text{(Me}_3\text{Sn})_4\text{Mo(CN)}_8]_n\). Each of the Mo\textit{(CN)}\textsubscript{8} groups is linked to eight adjacent Mo\textit{(CN)}\textsubscript{8} groups via bridging Me\textsubscript{3}Sn moieties. These eight Mo\textit{(CN)}\textsubscript{8} groups constitute the corners of a tetragonal unit cell\textsuperscript{388}. The Mo atoms itself are in the centre of a square planar antiprism with the cyanide groups occupying the corners. The tin atoms are again pentacoordinated. The heavier analogue \([\text{(Me}_3\text{Sn})_4\text{W(CN)}_8]_n\) is isostructural with the molybdenum compound\textsuperscript{388}.\n
![Diagram 164](image-url)
The organotin cyanometallates show a distinct host–guest chemistry based on a facile ion exchange, e.g. the $\text{Me}_3\text{Sn}^+$ cations were replaced by numerous organic and organometallic guest cations $G_n^{3+}$, such as $\text{NH}_4^+$, $\text{Bu}_4\text{N}^+$, $[\text{methylviologen}]^{2+}$, $[\text{Cp}_2\text{Co}]^+$ or $[\text{Cp}_2\text{Fe}]^+$. Typical examples for this type of reaction are given in equations 3 and 4.

$$[(\text{Me}_3\text{Sn})_4\text{M(CN)}_6]_n \xrightarrow{\text{Et}_4\text{NCl}} [(\text{Et}_4\text{N})(\text{Me}_3\text{Sn})_3\text{M(CN)}_6]_n \quad (3)$$

$$[(\text{Me}_3\text{Sn})_4\text{M(CN)}_6]_n \xrightarrow{[\text{Cp}_2\text{Co}][\text{ClO}_4]} [(\text{Cp}_2\text{Co})(\text{Me}_3\text{Sn})_3\text{Fe(CN)}_6]_n \quad (4)$$

The organotin cyanometallates were also used to intercalate a range of organic compounds such as thiazole and benzothiazole derivatives, polyaniline or polypyrrole.

Diorganotin cyanometallates have received less attention. The syntheses of $\{(\text{Bu}_2\text{Sn})_3[\text{Fe(CN)}_6]_2 \cdot 4\text{H}_2\text{O}\}_n$ and $\{(\text{R}_2\text{Sn})_3[\text{Co(CN)}_6]_2\}_n$ ($\text{R} = \text{vinyl}, \text{n-butyl}, \text{n-propyl}$) were reported, but only the cobalt-containing metallates were characterised by single crystal X-ray diffraction. The size of the organic groups at tin has little effect on the topology of the three-dimensional frameworks made up by bridging $\text{R}_2\text{Sn}$ moieties and distorted octahedral $\text{Co(CN)}_6$ units. Each tin atom is octahedrally coordinated by two carbon atoms of the organic substituents and four nitrogens of the $\text{Co(CN)}_6$ units. In the crystal lattice, channels are formed along the $c$-axis and are occupied by disordered alkyl groups. These channels have bottlenecks which, in the case of $\text{R} = \text{vinyl}$ (see structure below), prevent facile release of solvent molecules.

Similarly to the cyanometallates, rhodium anions $[\text{Rh(SCN)}_6]^{3-}$ and $\text{Me}_3\text{Sn}^+$ cations self-assemble to give the polymeric $[(\text{Me}_3\text{Sn})_3\text{Rh(SCN)}_6]_n$ in the solid state. In the three-dimensional framework, the rhodium atoms are linked via non-linear $\text{SCN}^−−\text{SnMe}_3−\text{NCS}$ spacers. It was suggested that a host–guest chemistry similar to the ion exchange reactions reported for cyanometallates might be possible.

4. Miscellaneous coordination polymers of organotin compounds

Inorganic acid derivatives. Organotin derivatives of polyfunctional inorganic acids usually self-assemble in the solid state to give chain polymers, layered compounds or three-dimensional networks. The carbonates, $(\text{R}_3\text{Sn})_2\text{CO}_3$ ($\text{R} = \text{Me}, \text{n-Bu}$), are illustrative examples of one-dimensional polymers containing helical chains and pentacoordinated tin atoms. In both compounds there are dangling $−\text{OSnR}_3$ side groups pointing away from the polymer backbone. Dimethylin bis(fluorosulphate), $\text{Me}_2\text{Sn(SO}_3\text{F})_2$ ($\text{R} = \text{Me}$, $\text{Et}$), and dimethylin thiosulphate, $\text{Me}_2\text{SnS}_2\text{O}_3$, are typical examples of layered compounds. Three-dimensional supramolecular structures were reported for compounds such as tris(trimethyltin) chromate hydroxide, $(\text{Me}_3\text{Sn})_3\text{CrO}_4(\text{OH})$, and dimethylin molybdate, $\text{Me}_2\text{SnMoO}_4$.

Coordination polymers with coordinative tin–sulphur bonding. Supramolecular self-assembly via coordinative tin–sulphur interactions to give polymeric organotin compounds is less distinctive than in coordination compounds with intermolecular tin–oxygen interactions. Intermolecular $\text{Sn–S}$ bonds were reported for the cyclic tin compounds $\text{R}_2\text{Sn(SCH}_2\text{CH}_2)_2$ ($\text{R} = \text{Me}, \text{Et}, \text{n-Bu}$) and $\text{Me}_2\text{Sn(SCH}_2\text{CH}_2)_2\text{S}$.
R = vinyl, n-Bu, Pr

coordination environment

framework (substituents at tin are omitted for clarity)
which self-assemble to give one-dimensional arrays of five-membered and eight-membered rings, respectively. In 167 an additional intramolecular Sn–S interaction was observed, which results in heptacoordinated tin atoms.

Diisothiocyanate derivatives of tri- and diorganotin compounds are self-assembled in the solid state. Trimethyl- and triphenyltin isothiocyanate, $\text{Me}_3\text{SnNCS}$ and $\text{Ph}_3\text{SnNCS}$, form infinite $\text{S}–\text{Sn}–\text{N}–\text{C}–\text{S}–\text{Sn}$ zigzag chains which are bent at sulphur. Dimethyltin diisothiocyanate, $\text{Me}_2\text{Sn(NCS)}_2$, consists of infinite chains formed along the c-axis. The coordination geometry at tin is best described as that of a strongly distorted octahedron with C–Sn–C angles of approximately 149°. The Sn–N bond distances in the tri- and diorganotin derivatives are in the range of 2.10–2.26 Å and the coordinative Sn–S bonds are in the range of 2.90–3.20 Å.

A more recent example of a one-dimensional polymer formed via S–Sn coordination is trimethyltin dithiotetraphenylimidodiphosphinate, $\text{Me}_3\text{Sn(}\text{SPPh}_2\text{NPPh}_2\text{S)}$ (168). The tin atoms are trigonal–bipiramidally coordinated with the two sulphur atoms occupying the axial positions. The Sn–S distances are quite different and amount to 2.517 and 3.627 Å. The dithioimidophosphinato ligand usually chelates a metal centre, but in 168 it bridges two tin atoms to give a helical chain polymer.
iii. Coordination polymers with coordinative tin–phosphorus bonding. Coordination polymers with coordinative tin–phosphorus bonds are rare. An intermolecular P–Sn coordination was previously suggested to occur in Me₂ClSnCH₂CH₂PPh₂ (169)\(^{409,410}\) which was based on NMR and \(^{119}\)Sn Mössbauer spectroscopic data. Recently, X-ray crystal structure analyses confirmed the previous assumption and showed a linear polymer with pentacoordinated tin atoms\(^{238}\). The phosphorus and the chlorine atoms are located in axial positions. The Sn–P distance in 169 amounts to 3.065(1) Å, which is comparable to the Sn–P distance of 3.078(2) Å in the monomeric, intramolecularly coordinated Me₂ClSnCH₂CH₂CH₂PPhBu-\(^{411}\). The bromo-substituted analogue of 169, Me₂BrSnCH₂CH₂PPh₂, was also suggested to adopt a polymeric chain structure similar to that established for 169\(^{238}\).

B. Organolead Polymers

Despite the strong tendency of lead compounds bearing electron-withdrawing substituents to self-assemble in the solid state, the coordination chemistry of supramolecular organolead compounds was much less investigated than the coordination chemistry of supramolecular organotin compounds. One reason might be the high toxicity of organolead compounds and another one the often very poor solubility of polymeric lead compounds. The large atomic size of lead should give coordination polymers with high coordination number environments at Pb and consequently such polymers might be rather different from those of the tin analogues. Some recent investigations were directed towards the coordination chemistry of inorganic lead salts with organic ligands to give polymeric inorganic–organic hybrid materials. These investigations include examples of coordination polymers of lead(II) halides, nitrate and thiocyanate with aliphatic
and aromatic nitrogen bases. In addition, poly(ethylene glycol) complexes of lead(II) nitrate and bromide were reported. Furthermore, supramolecular self-assembly was also reported to occur in compounds such as lead(II) alkoxydes, lead(II) phosphonates, lead(II) phosphinates, and lead(II) carboxylates. A fascinating example is the bimetallic compound $[\text{Pb}_2\text{Co}_3\text{CCO}_2]_n$ (170), which forms a chain-like array as a result of bridging carboxylate ligands (The carbonyl ligands of the tricobalt clusters are omitted). Pyrolysis of this compound gave a bimetallic material, which is a stable heterogeneous catalyst for the hydrogenation of 1,3-butadiene.

Furthermore, supramolecular polymeric arrays resulting from intermolecular lead–sulphur interactions were reported for some inorganic lead compounds, e.g. bis($O$-methylidithiocarbonato)lead(II), $[\text{Pb(S}_2\text{COMe})]_n$, bis(diethylidithiophosphinato)lead(II), $[\text{Pb(S}_2\text{PEt}_2)_2]_n$, bis(diphenyldithiophosphinato)lead(II), $[\text{Pb(S}_2\text{PPh}_2)_2]_n$, and bis(dimethyldithiophosphinato)lead(II), $[\text{Pb(S}_2\text{PMe}_2)_2]_n$. In the latter compound, dimeric units consisting of eight-membered Pb$_2$S$_4$P$_2$ rings are linked to give a one-dimensional polymer. A two-dimensional polymeric array was reported for the cyclic lead(II) dithiolate $[\text{Pb(DMIT)(DMF)})]_n$ (DMIT = 2-thioxo-1,3-dithiole-4,5-dithiolato).

1. Intermolecular organolead–halide coordination

Triorganolead halides are usually associated in the solid state, which was suggested first on the basis of infrared and Raman studies and later confirmed by X-ray crystallography. Usually, the lead atom is pentacoordinated with the halogen atoms located in the axial positions of a trigonal bipyramid and infinite $-\text{Pb}--\text{X}--\text{chains with unsymmetrical X--Pb--X links are formed. The two lead--halide distances in a given compound differ significantly. Thus in Me$_3\text{PbI}$ the lead--iodine distances amount to 3.038(2}$
and 3.360(2) Å, whereas the lead–bromine distances are 2.852(1) and 3.106(1) Å in Ph₃PbBr, and 2.885(2) and 2.985(2) Å in BzPb₂Br. All structures reported show zigzag chain conformations as a result of bent Pb–X–Pb fragments (171). The Pb–X–Pb angle depends strongly on the nature of the organic groups and the halide bound to Pb, e.g. in Me₃PbI, Ph₃PbBr and Ph₃PbCl the Pb–X–Pb angles amount to 108.10(5)°, 129.5(5)° and 134.0(5)°, respectively.

Diphenyllead dichloride, Ph₂PbCl₂, was reported to form a one-dimensional chain with the chlorine atoms symmetrically bridging adjacent lead atoms. The lead atoms are octahedrally coordinated with the phenyl rings mutually trans and the octahedra linked via opposite edges, giving a one-dimensional coordination polymer. The Pb–Cl distances amount to 2.795(6) Å and symmetrical Pb₂Cl₂ squares are formed (172). Vibrational studies on Ph₂PbX₂ (X = Cl, Br, I) were indicative for hexacoordinated lead atoms in Ph₂PbCl₂ and Ph₂PbBr₂, but pentacoordinated lead atoms in Ph₂Pbl₂.

The arene complex (η⁶-C₆H₆)Pb[AlCl₄]₂·C₆H₆ self-assembles in the solid state to give a chain structure which consists of AlCl₄ tetrahedra bridged by (η⁶-C₆H₆)Pb(II) moieties, and further AlCl₄ tetrahedra chelating the (η⁶-C₆H₆)Pb(II) moieties.

2. Intermolecular organolead–oxygen coordination

Only few examples of self-organised organolead compounds with oxygen-based donors have been reported to date. Triphenyllead hydroxide, Ph₃PbOH (173), is isostructural with its tin analogue and forms zigzag chains in which planar Ph₃Pb fragments are linked by hydroxide groups. In the unsymmetrical O–Pb–O fragment the lead–oxygen bond lengths amount to 2.37(2) and 2.44(2) Å. Triphenyllead 2-fluoro-4-nitrosophenolate is among the few structurally characterised organolead alkoxides. The latter forms a one-dimensional polymer via intermolecular Pb–O interactions of the p-nitroso substituent. One-dimensional zigzag chain structures with pentacoordinated lead atoms are also adopted by trimethyllead carboxylates (174). The intramolecular and the intermolecular Pb–O distances in trimethyllead acetate, Me₃Pb(OOCCH₃) (174a), amount to 2.327(24) and 2.555(25) Å, respectively, and in trimethyllead 2-furoate, Me₃Pb(OOCC₄H₃O) (174b), to 2.553(9) and 2.534(9) Å, respectively.
The crystal structure analyses of water-free diphenyllead diacetate revealed essentially different coordination modes of the carboxylate ligands when compared with the hydrated diphenyllead diacetate. The monohydrate, \([\text{Ph}_2\text{Pb(OAc)}_2]_2 \cdot \text{H}_2\text{O}\) (175), is a dimer in which the lead atoms are heptacoordinated with phenyl groups occupying the axial positions of two pentagonal bipyramids (pbp). The equatorial positions in the first pbp are occupied by four oxygens of two chelating acetate groups and a water molecule. The equatorial positions of the second pbp are occupied by three oxygens of two chelating acetate groups and a weak O–Pb interaction [Pb–O 2.71(2) Å] of an adjacent acetate group chelating the first lead atom. In addition, the coordinated water molecule forms a hydrogen bond to an adjacent acetate group.

In contrast, the water-free \(\text{Ph}_2\text{Pb(OAc)}_2\) (176) is a one-dimensional polymer containing octahedrally configurated lead atoms. One acetate group bridges [Pb–O 2.348(8), 2.547(8) Å] the molecular units to give infinite chains and the other OAc group is symmetrically chelating [Pb–O 2.364(9), 2.354(8) Å]. In contrast, di-o-tolyllead diacetate, \((\text{o-Tol})_2\text{Pb(OAc)}_2\), and phenyllead triacetate, \(\text{PhPb(OAc)}_3\), are monomeric in the solid state with hexacoordinated and heptacoordinated lead atoms, respectively, and unsymmetrically chelating acetate groups.
The crystal structure analyses of two polymeric triorganolead sulphonyl amides were reported. The trimethyllead derivatives $\text{Me}_3\text{PbN(SO}_2\text{Me)}_2$\textsuperscript{460} and $\text{Me}_3\text{PbN(SO}_2\text{F)}_2$\textsuperscript{461} both form similar, chain-like polymeric arrays in which the lead atoms are pentacoordinated with one oxygen and one nitrogen atom occupying the axial positions of a trigonal bipyramid. In $\text{Me}_3\text{PbN(SO}_2\text{F)}_2$, the Pb–N and Pb–O distances are similar and amount to 2.603(6) and 2.615(6) Å, respectively, whereas in $\text{Me}_3\text{PbN(SO}_2\text{Me)}_2$ essentially different bond lengths were observed [Pb–N 2.484(6), Pb–O 2.653(6) Å]. Interestingly, the tin analogue $\text{Me}_3\text{SnN(SO}_2\text{Me)}_2$ is also a chain-like polymer, but the pentacoordinated tin atoms are linked via two oxygens of the dimesylamide ligand, $[\text{N(SO}_2\text{Me)}_2]^–$\textsuperscript{462}. In contrast to the polymeric tin and lead compounds, the germanium analogue $\text{Me}_3\text{GeN(SO}_2\text{Me)}_2$\textsuperscript{460} is monomeric in the solid state.

3. Intermolecular organolead–sulphur coordination

Examples of supramolecular association as a result of intermolecular organolead–sulphur interactions are rare and compounds such as $\text{Me}_3\text{PbSMe}$ and $\text{Ph}_3\text{PbSPh}$ are monomeric in the solid state\textsuperscript{463}. In contrast, triphenylethyl pyridine-4-thiolate, 4-$\text{Ph}_3\text{PbSC}_5\text{H}_4$\textsuperscript{464}, is a chain polymer as a result of intermolecular N–Pb interactions. The cyclic dithiolate 2,2-diphenyl-1,3,2-dithiaplumbolane \textsuperscript{177}\textsuperscript{465} self-assembles in the solid state via intermolecular tin–sulphur interactions into a one-dimensional polymeric array. The intramolecular Pb–S bond lengths amount to 2.52(2) and 2.49(1) Å and the intermolecular Pb–S distances are 3.55(2) Å.

Supramolecular self-assembly was also observed in triphenylethyl dimethyltendiophosphinate, [Ph$_3$PbS$_2$PMe$_2$]$_n$(178)\textsuperscript{466}. The ditiophosphinate ligand unsymmetrically bridges two lead atoms of adjacent molecules to give a polymeric chain with pentacoordinated lead centres. The coordination environment at lead is best described as that of a distorted trigonal bipyramid with the phenyl groups in the equatorial and the sulphur atoms in the axial positions. The Pb–S distances amount to 2.708(4) Å and 3.028(4) Å.
4. Intermolecular organolead–nitrogen coordination

Early examples of structurally characterised organolead coordination polymers with Pb–N interactions are trimethyllead cyanide, $\text{Me}_3\text{PbCN}$, dimethyllead dicyanide, $\text{Me}_2\text{Pb}(\text{CN})_2$, and trimethyllead azide, $\text{Me}_3\text{PbN}_3$ (179). The latter compound forms a linear chain polymer with a $\mu_2$-N atom symmetrically bridging the pentacoordinated lead centres [Pb–N 2.54(1) Å]. The N–Pb–N angle [178.6(5)°] deviates only slightly from the ideal value of 180°.

\[
\begin{array}{c}
\text{Me} & \text{Pb} & \text{Me} \\
\text{N} & & \text{N} \\
& \text{Me} & \text{Me} \\
& \text{Pb} & \text{Me} \\
\end{array}
\]

(179)

In analogy to the organotin cyanometallates, some organolead homologues of the type $[(\text{Me}_3\text{Pb})_3\text{M(CN)}_6]_n$ (M = Fe, Co) and $[(\text{Me}_3\text{Pb})_4\text{M(CN)}_6]_n$ (M = Fe, Ru) were prepared by simply adding a saturated aqueous solution of Me$_3$PbCl to concentrated solutions of $\text{K}_3[\text{M(CN)}_6]$ or $\text{K}_4[\text{M(CN)}_6]$. Structural data for these compounds based on X-ray crystallography are rare and mainly vibrational and solid state NMR spectroscopy were used to characterise the organolead cyanometallates.

A fully characterised compound is $[(\text{Me}_3\text{Pb})_3\text{Co(CN)}_6]_n$. The supramolecular organolead cyanometallate consists of a three-dimensional polymeric network with the sequence $-\text{Co}--\text{C}≡\text{N}--\text{Pb}--\text{N}≡\text{C}$. The network involves Me$_3$Pb$^+$ cations and wide parallel channels whose walls are internally coated by the methyl groups of the Me$_3$Pb$^+$ moieties. A second structurally characterised example of an organolead cyanometallate is $[(\text{Me}_3\text{Pb})_4\text{Fe(CN)}_6·2\text{H}_2\text{O}]_n$, which consists of infinite puckered layers. The sequences $-\text{Fe}--\text{C}≡\text{N}--\text{Pb}--\text{OH}_2$ within each layer form hydrogen bridges between adjacent layers. The anhydrous analogues were obtained after prolonged drying in vacuo at 60–80°C, but their exact structure is not known so far. The lead compounds $[(\text{Me}_3\text{Pb})_4\text{Fe(CN)}_6]_n$ do not display the unique ion-exchange properties of their tin analogues. For example, stirring a suspension of $[(\text{Me}_3\text{Pb})_4\text{Fe(CN)}_6]_n$ with an aqueous solution of Et$_4\text{NCl}$ did not give $[(\text{Et}_4\text{N})(\text{Me}_3\text{Pb})_3\text{Fe(CN)}_6]$ and Me$_3$PbCl. In contrast, $[(\text{Me}_3\text{Sn})_4\text{Fe(CN)}_6]_n$ is almost quantitatively transformed into $[(\text{Et}_4\text{N})(\text{Me}_3\text{Sn})_3\text{Fe(CN)}_6]$ by the release of Me$_3$Sn$^+$. However, it is possible to prepare by cocrystallisation of the appropriate cations and anions host–guest systems of the type $[(\text{G})(\text{Me}_3\text{Pb})_3\text{Fe(CN)}_6]_n$ with G = Et$_4$N$^+$ or Cp$_2$Co$^+$. In addition, the intercalation of heterocyclic organic guest molecules in the host system $[(\text{Me}_3\text{Pb})_4\text{Fe(CN)}_6]_n$ was investigated and compounds of the general type $[(\text{D})(\text{Me}_3\text{Pb})_3\text{Fe}^{II}_x\text{Fe}^{III}_1-x\text{Fe}(\text{CN})_6]_n$ (0 ≤ x ≤ 1; D = oxidised cationic organic guest donor) were synthesised.

I. INTRODUCTION

Germanium is the middle element of Periodic Group IVA. The other elements in the Group have extensive and important biochemistries. Little attention has been paid to germanium chemically or biologically until it was found as a decay product of some nuclear disintegrations. Later, when its semiconductor property was found, interest grew. In 1962 van der Kerk and coworkers1 demonstrated that triorganylgermanium acetates had antifungal activities. Then in 1968 carboxyethylgermanium sesquioxide (GeCH₂CH₂COOH)₂O₃ (Ge-132) was synthesized by Asai².³ His goal of synthesizing water-soluble organoger- manium compounds originated from his conception that germanium should have some important significance for life, since this element is distributed universally in coal and is particularly present in valued Chinese herbs and healthy vegetables such as ginseng, garlic, oats or soya beans²,⁴ and is very well absorbed after ingestion (>90%). In the 1970s, dietary germanium supplements became very popular due to the alleged therapeutic value of germanium (stimulation of iron consumption and haemoglobin production). In 1994 the first organogermanium pharmaceutical propagermanium was launched in Japan under the trade name Serocion® (Sanwa Kagaku Kenkyusho Co., Ltd.). Its biological activity
spectrum includes protection against viruses, immunostimulation and hepatoprotection. Propagermanium — belonging to germsesquioxanes — has low toxicity.

This achievement has stimulated further investigations of the biological activity, not only of germsesquioxanes but also of other classes of low toxic organogermanium compounds.

Today, numerous organogermanium compounds possessing antitumor, immunomodulating, interferon-inducing, radioprotective, hypotensive and neurotropic properties have been synthesized\(^4\),\(^5\). The most intensively investigated organogermanium compounds are germsesquioxanes \([(\text{GeCHR}^1\text{CHR}^2\text{COOH})_2\text{O}_3]\), (1, \(\text{R}^1 = \text{R}^2 = \text{H}\), 2-carboxyethylgermanium sesquioxide, Ge-132, repargermanium, rexagermanium, proxigermanium, propagermanium, Serocion\(^\circledR\); \(\text{R}^1, \text{R}^2 = \text{alkyl, aryl, hetaryl}\), 2-(3-dimethylaminopropyl)-8,8-diethyl-2-aza-8-germaspiro[4,5]decane (2, spirogermanium), germatranes (3), germyporphyrines (4) and many germyl-substituted heterocycles (mainly derivatives of furan, thiophene, isoxazoline, uracil). Since biological investigations have become more important, some reviews on the biological properties of organogermanium compounds have appeared\(^2\)–\(^15\).

II. TOXICITY

Toxicological studies have demonstrated that most organogermanium compounds tested were less toxic than the corresponding organosilicon and organotin analogues\(^4\),\(^5\). On the other hand, in some cases nephrotoxicity caused by long-term administration of germanium-containing organic preparations in large doses was documented\(^12\),\(^14\)–\(^24\).
The acute toxicity of organogermanium compounds depends on the type of organogermanium compound, the substituent at the germanium atom and the coordination number of the latter ranging from nontoxic compounds (tetraalkylgermanes, germanols, germoxanes, adamantyl derivatives of germanium) with LD$_{50}$ more than 3000–5000 mg kg$^{-1}$ to highly toxic derivatives having LD$_{50}$ about 11–20 mg kg$^{-1}$ (trifluoroacetylfurylgermanes, thiénylgermatranes).

A group of low toxic germatranes is presented in Table 1. Their mean lethal dose (LD$_{50}$) at intraperitoneal (i.p.) administration varies from 10,000 to 3000 mg kg$^{-1}$. This group of compounds includes the derivatives of pyrrolidone ($\beta$-pyrrolidonyethyl being less toxic than $\alpha$-isomer), adamantane, phthalimide and $N,N'$-dialkylaniline. 1-Hydroxygermatrane (LD$_{50}$ 8400 mg kg$^{-1}$) is a low toxic compound, but the trimethylsilylation of its hydroxyl group increases the toxicity 2.4 times. (2-Methoxycarbonylpropyl)germatrane (LD$_{50}$ 6820 mg kg$^{-1}$), vinylgermatrane (LD$_{50}$ 5600 mg kg$^{-1}$) and $p$-fluorobenzoylaminomethylgermatrane (its chloro derivative being more toxic) also belong to this group of low toxic compounds.

The group of compounds with moderate toxicity (Table 2) includes chloromethylgermatrane (LD$_{50}$ 2960 mg kg$^{-1}$; its bromomethyl derivative appears considerably more toxic with LD$_{50}$ 355 mg kg$^{-1}$), 2- and 4-pyridylethylgermatranes (LD$_{50}$ 2820 and 2580 mg kg$^{-1}$), tris(2-thienyl)siloxy-, methyl(2-thienyl)siloxy-, dimethyl(2-thienyl)siloxy-, diphenylsiloxy- and triphenylsiloxygermatranes (LD$_{50}$ ca 2500, 1000, >2500, 2240, >1000 mg kg$^{-1}$), 2- and 3-furyl-, 2-furfuryl-, methyl(2-furyl)siloxy-, 4-bromo-3-thienyl- and $\beta$-styrylgermatrane (2050, 1630, 2960, 1030, 2240, 1410 mg kg$^{-1}$, respectively). Triphenylgermoxy-, diphenylmethylsiloxy-, $\alpha$-naphtylphenylsiloxygermatrane and all benzylgermatranes also possessed moderate toxicity (LD$_{50}$ >1000 mg kg$^{-1}$).

RCH$_2$-substituted germatranes (Tables 2 and 3), where R = diethylamino-, bromo-, 2-thienyl, form a group of more toxic compounds (LD$_{50}$ 325–350 mg kg$^{-1}$). 1-Hydrogermatrane reveals a similar toxicity (LD$_{50}$ 320 mg kg$^{-1}$).

</table>

All furylgermatranes are less toxic than corresponding thienyl derivatives$^{10}$. 2-Thienyl-, 5-methyl-2-thienyl-, 5-bromo-2-thienyl- and 2-methyl-3-thienylgermatranes are highly toxic compounds with LD$_{50}$ values within the 16.5–20.5 mg kg$^{-1}$ range (Table 3). The position of bromine atom and the germatranyl group in the thiophene ring...
dramatically influences the toxicity of a compound: it varies from the very toxic 5-bromo-2-thienylgermatrane to nontoxic 3-bromo-4-thienylgermatrane (Table 3). 2-substituted isomers belonging to the thiophene series appear to be the most toxic, while in the furan series the 2-derivatives are less toxic than the 3-isomers. Phenylgermatrane is two times less toxic than 2-thienylgermatrane (16.5 mg kg$^{-1}$) but still exhibits high toxicity (LD$_{50}$ 35.5 mg kg$^{-1}$). Introduction of a methyl group in the para-position of a phenyl ring decreases the toxicity 2 times (LD$_{50}$ 70 mg kg$^{-1}$).

The high toxicity of phenyl- and thienylgermatranes cannot be explained either by the presence of the tricyclic germatrane ring with the pentacoordinated germanium atom or by the presence of the $\pi$-electron system in the substituent. Alkylgermatranes containing the same germatrane system and vinylgermatrane (possessing a $\pi$-bond) are nontoxic compounds (Table 1). Hydrolysis of the Ge–O bond decreases the toxicity by more than 500 times. Both products of Ge–O bond hydrolysis—germanic acid (LD$_{50}$ ca 2000 mg kg$^{-1}$) and triethanolamine (LD$_{50}$ 1450 mg kg$^{-1}$)—are also less toxic than the starting 2-thienylgermatrane. As the mechanism of arylgermatrane biological activity is not yet known, one can speculate that both parts of the molecule—the germatrane system (for binding to the receptor?) and the aryl group bound directly to the germanium atom (for toxic bioarylation; 2-thienylmethyl- and benzylgermatranes are less toxic, LD$_{50}$ 325 and >1000 mg kg$^{-1}$)—are important for the exhibition of high toxicity.

Most of the organylgermsesquioxanes (RGeO$_{1.5}$)$_n$ and organylgermsesquithianes (RGeS$_{1.5}$)$_n$ tested are low toxic compounds.

The toxicity of various germesquioxanes (proxigermanium, propagermanium, Ge-132, 2-carboxyethylgermsesquioxane) has been investigated.

2-Carboxyethylgermsesquioxane exhibits acute toxicity for mice and rats with a mean LD$_{50}$ value of 6000–10000 mg kg$^{-1}$ (p.o., i.p.) and 4500–5700 mg kg$^{-1}$ (i.v.) Sub-chronic oral toxicity of [(HOOCCH$_2$CH$_2$Ge)$_2$O$_3$]$_n$ (in rats of 1 g kg$^{-1}$ day$^{-1}$ during six months) has been reported. Daily oral administration of Ge-132 (120 mg kg$^{-1}$) for 24 weeks exhibited no toxic effects in mice.

Oral administration of proxigermanium for a year at 750 mg kg$^{-1}$ day$^{-1}$ induced diarrhea in rats. However, it has been found that a dose of 83 mg kg$^{-1}$ is not toxic. Proxigermanium administered in a dose of 15–240 mg/body has not affected physiological function in healthy volunteers.

The compound is not embriotoxic, teratogenic, mutagenic, carcinogenic or anti-genic. Oral administration of proxigermanium does not affect fertility at 350, 700 and 1400 mg kg$^{-1}$ day$^{-1}$ during 60 days before and at mating in male rats and during 14 days before, and at and during 7 days after mating in female rats.

The histological investigation revealed no significant renal toxic effects of propagermanium when administered at a high dose for 8 weeks. Propagermanium administration was not associated with any alteration in the changes induced by Adriamycin or mercuric chloride. This confirms that propagermanium may be a safe compound for use in individuals with compromised kidneys. On the other hand, case reports on the nephro-toxicity of organogermanium preparations (high doses, long-term administration) have been published. One-month oral subacute toxicity of propagermanium has been studied.

Hydroxamic acid (O$_{1.5}$GeCH$_2$CH$_2$CONHOH)$_n$, its sodium salt and 1-(2-pyrrolidonyl)ethylgermsesquioxane appear to be low toxic compounds as well, their LD$_{50}$ values exceeding 5000 mg kg$^{-1}$. 3,5-Dimethylpyrazolylmethylgermsesquioxane (n = 6) exhibits acute toxicity with a mean LD$_{50}$ value of 708 mg kg$^{-1}$.40.
Cyclic and acyclic organogermanium derivatives of cysteamine and methylcysteamine exhibit toxicity within the 150–1500 mg kg$^{-1}$. Introduction of the germatranyl group into aminothiol molecules decreases the toxicity of the compounds. Germadithioacetals showed moderate toxicity (100–800 mg kg$^{-1}$). Diisoamyldithiagermocane, germylated sulfides and di-$n$-hexylpyridinoxathiagermolane are low toxic compounds (800 to >1500 mg kg$^{-1}$). Subacute toxicity of tetra(2-carboxy-2-aminoethylmercapto)germanium has been studied.

The acute toxicity of a new class of germilisoxazolin-2-yl derivatives (5) has been investigated. These compounds have medium toxicity (mean LD$_{50}$ values within 355–708 mg kg$^{-1}$). The introduction of a methylene group between the triethylgermyl group and the isoxazoline ring, as in the case of germatranes (Table 2), decreases the toxicity 2.2-fold.

![Chemical structure](image)

(5) R = 2-, 3-, 4-pyridyl, n = 0; 2-, 3-pyridyl, n = 1

Trifluoroacetyl derivatives of furan possess a wide range of toxicity (Table 4). In this type of compounds germanium derivatives are more toxic than the corresponding silicon derivatives. The triethylgermyl derivative is a highly toxic compound, LD$_{50}$ 11.2 mg kg$^{-1}$. It is interesting to note that trimethyl derivatives of Ge and Si analogues have comparable toxicity, but substitution of the methyl group by ethyl dramatically changes the toxicity. The germanium derivative becomes 200 times more toxic than the silicon analogue (see Table 4).

The experimental evaluation of acute toxicity of germil(silyl)-substituted furfurylidene Meldrum acid (Table 5) has demonstrated that the introduction of the trimethylgermyl group lowers the toxicity of the compound by ca 4 times. On the other hand, the introduction of the trimethysilyl group does not change significantly the toxicity of the unsubstituted derivative. The carbon analogue is the most toxic derivative in this series of compounds.

Preclinical toxicological evaluation of spiogermanium (2-(3-dimethylaminopropyl)-8,8-diethyl-2-aza-8-germaspiro[4,5]decane) (2) in white mice and beagle dogs confirmed a lack of bone-marrow toxicity and pointed to a dose-limiting toxic effect of the spiogermanium compound on the central nervous system, manifested in dogs by piloerection, nystagmus,

tremor and lethal dose generalized seizures\(^{11,47,48}\). A neurotoxicity of the spirogermanium at doses of 32–60 mg m\(^{-2}\) has been observed in clinical trials as well\(^4\). A dose-limiting toxicity has been observed in patients\(^{49}\). Spirogermanium is rapidly removed from the plasma and appears not to be accumulated in tissues\(^{14}\).

III. NEUROTROPIC ACTIVITY

The neurotropic activity of gematranaes, germesquioxanes, germyl-substituted amines, imines, hydroxamic acids, isoxazolines and organogermanium derivatives of furan and adamantane has been studied\(^4,5,10,40,44,50–54\).

The influence of siloxy- and germoxygematranaes \( \text{R}_n \text{MOGe(OCH}_2\text{CH}_2)_3\text{N} \) (M=Si, Ge) on locomotor activity and muscle tone parameters was low. Trimethylsiloxy-, triphenyl siloxy- and triphenylgermylsiloxygematranaes in doses up to 500 mg kg\(^{-1}\) do not affect the parameters mentioned. In rotating-rod, tube and traction tests di(2-thienyl)methyl-, tri(2-thienyl)- and \( \alpha \)-naphtylphenylsiloxygematranaes have ED\(_{50}\) within the 178–410 mg kg\(^{-1}\) range, and (2-thienyl)dimethylsiloxygematrane between 70 and 250 mg kg\(^{-1}\). 1-Hydroxygematrane (ED\(_{50}\) 0.0015 mg kg\(^{-1}\)) exhibits the highest depressant activity on the central nervous system (CNS)\(^{10}\).

1-Hydroxygematrane prevents the hypoxia-caused death in experimental animals. The prolongation of life-span for a mouse under hypoxic hypoxia (i.p. administration, 50 mg kg\(^{-1}\)) is more than doubled under the influence of gematrano. Silylation and gemylation of its hydroxy group significantly decrease the antihypoxic properties as measured by the activity in percentage vs. control (100%) (Table 6). Introduction of alkyl substituents in position 5 of the thiophene ring does not significantly change the antihypoxic activity.

In most cases the hetarylgematranaes [\( \text{R(CH}_2\text{)}_n \text{Ge(OCH}_2\text{CH}_2)_3\text{N} \)] with gematranyl group connected directly to the carbon atom (\( n = 0 \)) possess higher toxicity and higher CNS activity\(^{10}\).

Some regularities have been observed in the series of 5-membered nitrogen heterocycles (Table 7). The 1-isomer of pyrrolidonylethylgematrane is more active than the 2-isomer. Introduction of a second carbonyl group in the ring (R = succinimidomethyl) increases the antihypoxic effect of the compound. Introduction of a double bond (R = maleinimidomethyl) leads to the further increase in the activity (145.5%). The condensation of the latter with the benzene ring (R = phthalimidomethyl) reduces the activity while the substitution of one carbonyl group for the SO\(_2\) group increases the protecting properties.

4-(Dimethylamino)phenylgematrane, belonging to the series of nitrogen-containing phenylgematranaes, shows reliable antihypoxic activity, prolonging the life by 55.4%.

5-(1-Cyclohexenyl)-1-germatranyl methyl-5-methylbarbituric acid has the highest antihypoxic activity among the nitrogen-containing compounds (Table 7).

Furyl- and phenylgermatranes are more active against hypoxia than thienylgermatranes and compounds with a nitrogen-containing substituent (Table 8). The protecting potency of 2-furylgermatrane is higher than that of the 3-isomer. Insertion of the CH₂ group between the aromatic or heteroaromatic ring and the germatrane group reduces the activity in all cases (Table 8). Introduction of a methyl group in position 5 of the thiophene ring increases
the antihypoxic activity by 2.6 times. In bromobenzylgermatranes, the antihypoxic activity strongly depends on the position of bromine atom: \( \alpha \)- and \( \beta \)-derivatives are 3 times more active than \( m \)-bromobenzylgermatrane. The \( \beta \)-styrylgermatrane exhibits the highest antihypoxic activity.

Furylgermatranes exhibit stimulating activity in an ethanol anaesthesia test (Table 9). In the thiophene series 2-isomer is a stimulant as well, while the 3-isomer acts as CNS depressant. Introduction of a methyl group increases the stimulating activity of the 2-isomer and the depriming properties of the 3-isomer. Introduction of an ethyl group in position 5 changes the action mode of the 2-isomer from stimulation of CNS to its depression. Some regularities have been observed in aromatic derivatives. All substituted arylogermatranes exhibit a stimulating activity in the ethanol anaesthesia test. \( p \)-Tolylgermatrane has the highest antidepressant activity (68%). Unsubstituted arylogermatranes possess depriming properties. Most tested aryl- and hetarylgermatranes prolong the duration of hexobarbital anaesthesia. High activity is observed for \( p \)-bromobenzyl- (195%) and 5-ethyl-2-thienyl derivatives (205%). The 2-furfuryl derivative is even more active (236.6%). It is interesting to note that in some cases the mode of anaesthetic activity depends on the anaesthetic agent. For example, all furylgermatranes prolong the duration of hexobarbital anaesthesia but shorten the ethanol anaesthetic properties (Table 9).

1-Hydroxygermatrane shortens the duration of ethanol anaesthesia (Table 10). Triphenylgermylation of its hydroxyl group increases the stimulating activity while the silylation in most cases prolongs the ethanol anaesthesia. Methyl(2-furyl)siloxygermatrane and diphenylsiloxygermatrane were the most active compounds in prolongation of hexobarbital anaesthesia.

1-Hydroxygermatrane (p.o.) has been shown to lack any protective activity in corazol-, maximal electric shock- and strychnine-induced convulsions. Hydroxygermatrane hydrate does not prevent tremor caused by the N- and M-ergic substances nicotine and arecoline. However, when thiostemicarbazide was used as a convulsion-inducing agent, germatranol in doses of 100 and 250 mg kg\(^{-1}\) noticeably increased the latent period of the beginning of the first tremor attack. This fact provides indirect evidence for the participation of GABA in the neurotropic mechanism of the compound. With the same dose, germatranol hydrate displays serotonin-blocking activity.

Arylogermatranes were more active than hetaryl derivatives in memory improvement tests (Table 11). Phenylgermatrane, \( p \)-tolylgermatrane, \( p \)-fluorophenylethynylgermatrane, benzylgermatrane and \( \alpha \)- and \( p \)-bromobenzylgermatranes completely prevented animals from retrogradal amnesia caused by electric shock.

Germinol generally undergo dehydration to form the corresponding germonoxanes. Tricyclohexylgermatrane is the sole example which was successfully isolated and studied. This compound in doses of 35–100 mg kg\(^{-1}\) showed some sedative activity, i.e., reduced the duration of phenamine stereotype behavior, and in a dose of 35 mg kg\(^{-1}\) lowered the body temperature by 3°C (or even more) in 50% of the experimental animals. On changing from germatranes to germesquioxanes with the same substituent at the germanium atom, the effect of the latter on locomotor activity, muscle tone and body temperature is increased to some extent. It has been noted that 3,5-dimethylpyrazolymethylgermesquioxanes within their neurotropic activity spectrum have the ability of activating action, in that they strengthen the phenamine stimulation by 55.3 and 34.6%, respectively, and reduce reserpine-depressant activity (ptosis and hypothermia) (Table 12).

as therapeutic agents for brain aging. Germanium-132 can antagonize the damage of neural behavior caused by lead.

Furan-containing germyl-substituted amines have moderate toxicity (LD$_{50}$ 205–234 mg kg$^{-1}$). Their methylammonium derivatives have been found to possess the highest toxicity (LD$_{50}$ 81.5 mg kg$^{-1}$) in this group of compounds. The methyldiethylammonium compound shows the highest depressant activity in rotating-rod, tube, traction and hypothermia tests. Substitution of the ethyl groups for methyl groups in the ammonium derivatives evokes a considerable decrease in depressant activity component (Table 13).
It has been found that the neurotropic activity of 2-trialkylgermyl-5-trifluoroacetylfurans depends on the alkyl substituent at the germanium atom: the 2-triethylgermyl derivative exhibits the highest activity in the hexobarbital anaesthesia test and prolongs its duration by 137%. The 2-trimethylgermyl derivative exhibits a stimulating activity in the ethanol anaesthesia test and completely prevents animals from retrogradal amnesia (Table 14). All germyl-substituted compounds possess anti-Corazol potency; however, the trimethylsilyl and tert-butyl derivatives were more active. The pharmacological effects of phenamine are depressed by all the trifluoroacetyl derivatives. It has been found that the neurotropic activity of 2-trialkylgermyl-5-trifluoroacetylfurans depends on the alkyl substituent at the germanium atom: the 2-triethylgermyl derivative exhibits the highest activity in the hexobarbital anaesthesia test and prolongs its duration by 137%. The 2-trimethylgermyl derivative exhibits a stimulating activity in the ethanol anaesthesia test and completely prevents animals from retrogradal amnesia (Table 14). All germyl-substituted compounds possess anti-Corazol potency; however, the trimethylsilyl and tert-butyl derivatives were more active. The pharmacological effects of phenamine are depressed by all the trifluoroacetyl derivatives.

All germyl-isoxazolin-2-yl pyridine derivatives exhibit low activity in rotating-rod, tube and traction tests. The 2-pyridyl-substituted germylisoxazoline ($n = 0$) was the most active in increasing the duration of thiopental anaesthesia by 109%, while the 3-pyridine-substituted analogue decreased it by 25.9% (Table 15). The introduction of the methylene group between the triethylgermyl group and the isoxazoline ring caused an opposite effect, i.e. shortening the anaesthesia time by 28% and by 70%44. Germyl-isoxazolin-2-yl derivatives possess low antihypoxic activity. The stimulating effects of phenamine strengthened under the influence of 4-(5′-triethylgermyl-3′-isoxazoliny)pyridine hydrochloride by 55.3%. (3-Ethyl-4-triphenylgermylisoxazolinyl-2)-5-carboxylic acid ethyl ester exhibits...

the highest effect (by 104%)$^{44}$. 2-(5'-Triethylgermylmethyl-3'-isoxazolinyl)pyridine hydrochloride and 3-(5'-triethylgermylmethyl-3'-isoxazolinyl)pyridine hydrobromide in comparatively small doses (50 mg kg$^{-1}$) completely prevented retrogradal amnesia caused by electric shock.

The germanium derivative of Meldrum’s acid (Table 16) exhibits the highest anti-Corazol activity (262%) and depressed pharmacological effects of phenamine by 55.5% $^{46}$.

Neurotropic activity of propiohydroxamic acids and isobutyrohydroxamic acids $^6$ has been studied$^5$.$^{10}$. When $\beta$-trimethylgermylpropiohydroxamic acid is administered p.o. in doses of 20 and 250 mg kg$^{-1}$ it prolonged the life of animals under hypoxic hypoxia by 70–149.2%. In very low doses (5 mg kg$^{-1}$) it favorably affects the elaboration of passive conditional responses. At higher doses the depressant activity appears. This is confirmed by the hexenal anaesthesia test. Thus, $\beta$-trimethylgermylpropiohydroxamic acid in doses of 5 and 50 mg kg$^{-1}$ reduces the duration of hexenal anaesthesia by 34.5 and 20.1%, respectively, whereas a large dose (250 mg kg$^{-1}$) prolongs this parameter by 282.1%. The pronounced protective action of $\beta$-trimethylgermylpropiohydroxamic acid on strychnine-induced convulsions is the evidence for its influence on the spinal cord. Obviously, the mechanism of $\beta$-trimethylgermylpropiohydroxamic acid action implies an influence on the central serotoninergic processes. During its application in large doses (100 and 250 mg kg$^{-1}$) GABA-ergic processes are involved as well$^{10}$.

<sup>a</sup>Ad = 1-adamantyl.

governing the toxic properties and neurotropic activity of these compounds have been revealed. Thus, comparison of 1-adamantylgermatrane with 1-adamantyl germatrandione has shown that the introduction of two carbonyl groups into the germatrane ring increases to some extent the toxicity and decreases the anticonvulsant activity of the compound. At the same time, the latter has the highest depressant activity among adamantylgermatranes. The 1-adamantyl derivative with two methylene groups between the germanium atom and the adamantyl group is more toxic than the corresponding substance containing three methylene groups. On changing from 2-(1-adamantyldimethylgermyl)propionic acid to β-(1-adamantyldimethylgermyl)propiohydroxamic acid, the toxicity of the compound increased 1.8-fold. It has been found that some 1-germyladamantanes increase the Corazol dose, causing tonic convulsions with lethal outcome. Duration of hexenal anaesthesia is statistically increased by 2-(1-adamantyldimethylgermyl)propionic acid and 1-adamantylgermatranedione, while under the influence of 1-adamantylethylgermane it is decreased. All the organogermanium derivatives of adamantane studied at a dose of √50 mg kg<sup>−1</sup> exhibit antihypoxic activity, mostly expressed in 1-adamantylgermatrane, germatrandione and 1-(γ-trimethylgermyl)propyladamantane. The 1-adamantylamide of trimethylgermylpropionic acid decreased hypothermia in a dose of 50 mg kg<sup>−1</sup> by 3 °C and reserpine-induced ptosis by 25%.

1-Adamantylgermatrane has been studied more thoroughly during its administration to the stomach in doses from 5 to 250 mg kg<sup>−1</sup>. Administer p.o., it also reveals pronounced antihypoxic activity which increases with dose. 1-Adamantylgermatrane in doses of 50–250 mg kg<sup>−1</sup> reveals antihypoxic potency also at haemic hypoxia.<sup>10</sup>

A reproducible effect of 1-adamantylgermatrane on the pharmacological activity of phenamine, 5-oxytryptophan and strychnine has been observed. In the mechanism of action of 1-adamantylgermatrane, a considerable role is played by its M-cholinemimetic influence (i.e. it strengthens the adrenaline tremor) and GABA-ergic structure.

The antimuscarnic activity of (hydroxymethyl)diorgano(2-piperidinoalkyl)germanes has been studied.<sup>58–60</sup>

The (R)- and (S)-enantiomers of (hydroxymethyl)diorgano(2-piperidinoethy1)germanes [Ph(−Hex)Ge(CH<sub>2</sub>OH)CH<sub>2</sub>CH<sub>2</sub>NR<sub>2</sub>, Ph(−Hex)Ge(CH<sub>2</sub>OH)CH<sub>2</sub>CH<sub>2</sub>NR<sub>2</sub> · CH<sub>3</sub>I] and their
achiral derivatives \([\text{Ph}_2\text{Ge(CH}_2\text{OH})\text{CH}_2\text{CH}_2\text{NR}_2, \text{Ph}_2\text{Ge(CH}_2\text{OH})\text{CH}_2\text{CH}_2\text{NR}_2 \cdot \text{CH}_3\text{I, (c-Hex)}_2\text{Ge(CH}_2\text{OH})\text{CH}_2\text{CH}_2\text{NR}_2, (c-Hex)_2\text{Ge(CH}_2\text{OH})\text{CH}_2\text{CH}_2\text{NR}_2 \cdot \text{CH}_3\text{I, NR}_2 = \text{piperidino}]\) exhibited their affinities for muscarinic M1, M2, M3 and M4 receptors by functional pharmacological experiments (M1, rabbit vas deferens; M2, guinea-pig atria; M3, guinea-pig ileum) and radioligand binding experiments (M1, human NB-OK 1 cells; M2, rat heart; M3, rat pancreas; M4, rat striatum). According to these studies\(^{59,60}\) all the germanes and the related silicon analogues behaved as simple competitive antagonists at muscarinic M1–M4 receptors. The \((R)-\text{enantiomers of the Ge/Si pair Ph(c-Hex)Ge(CH}_2\text{OH})\text{CH}_2\text{CH}_2\text{NR}_2\) and \(\text{Ph(c-Hex)Ge(CH}_2\text{OH})\text{CH}_2\text{CH}_2\text{NR}_2 \cdot \text{CH}_3\text{I}\) exhibited higher affinities (up to 26-fold) for M1–M4 receptors than their corresponding \((S)-\text{antipodes, the stereoselectivity ratios being higher at M1, M3 and M4 than at M2 receptors.}\)

4,4-Dimethyl-4-germa-\(\gamma\)-butyrolactone strongly inhibits dipeptidylcarboxypeptidase degradation of enkephalins\(^61\). This result suggests that the compound may be effective in the physiological pain-regulation system \textit{in vivo}.\)

\textbf{IV. CARDIOVASCULAR ACTIVITY}

Cardiovascular activity of 2-carboxyethylgermanium sesquioxane (Ge-132) has been studied in rats anaesthetized with urethane \((i.p.)\). It produced a dose-related reduction in either the mean arterial pressure or the heart rate. The data indicate that Ge-132 induces both hypotension and bradycardia by promoting an activation of the parasympathetic efferent mechanisms and an inhibition of the sympathetic efferent mechanisms. On the other hand, following \(i.p\). injection of Ge-132, increased grooming and head swaying were provoked. Thus, it appears that Ge-132 acts through the catecholaminergic mechanisms in the brain to induce locomotor stimulation in rats\(^62\).\)

The germyl- and silyl-substituted adrenaline derivative \(3,4\)-bis(trimethylsiloxy)-4-\(\alpha\)-(trimethylsiloxy)-\(\beta\)-(methyl)(triethylgermylamino)ethylbenzene \((0.1 \text{ mg kg}^{-1}, i.v.)\) increased the blood pressure twice as effectively than the same dose of adrenaline. This compound is 7 times less toxic than adrenaline\(^63\).\)

4-(5-Trimethylgermyl-2-furyl) substituted 1,4-dihydropyridine administered \(i.v\). in a 0.05 \(\text{mg kg}^{-1}\) dose increased the blood flow in the common carotid of cats by 31\%, and in a 0.1 \(\text{mg kg}^{-1}\) dose it dilates the coronary vessels by 11\% and decreased the arterial pressure by 12\%\(^5\).\)

The vasodilating, anticoagulant and cardioprotective activities of 5-germanium substituted isoxazolines-2 have been studied \textit{in vitro} and \textit{in vivo}\(^64\). 2-(5'-Triethylgermyl-3'-isoxazolinyl)pyridine hydrochloride and 3-(5'-triethylgermyl-3'-isoxazolinyl)pyridine hydrochloride induced significant vasodilatation, the latter being the most active. It has been found that silicon analogues were less active. Insertion of the methylene group between the germanium and the isoxazoline ring reduced the vasodilating activity. All the investigated germylisoxazolinyl substituted pyridines prolonged the coagulation time. 3-(5'-Triethylgermyl-3'-isoxazolinyl)pyridine hydrochloride was the most active anticoagulant among the studied compounds. In the experiments on anaesthetized rats, 2-(5'-triethylgermyl-3'-isoxazolinyl)pyridine hydrochloride and 3-(5'-triethylgermyl-3'-isoxazolino)pyridine hydrochloride protected animals from ischaemia; the 3-isomer also protected the heart from ventricular fibrillation.\)

\textbf{V. ANTITUMOR, ANTIVIRAL AND IMMUNOMODULATING ACTIVITY}

2-(3-Dimethylaminopropyl)-8,8-diethyl-2-aza-8-germaspiro[4,5]decane (spirogermanium) was the first organogermanium compound tested clinically as an antitumor
agent\textsuperscript{4,5,11,48,65–76}. The described mode of action is inhibition of protein synthesis with secondary suppression of RNA and DNA synthesis. It has been reported that spirogermanium has also antiarthritic and suppressor cell-inducing activity\textsuperscript{77}. Phase I clinical study\textsuperscript{49,78,79} showed good drug tolerance. Further evaluation in Phase II revealed consistent neurotoxicity, ranging from dizziness to disorientation, as well as mild hematological and hepatic toxicity. Modest activity was demonstrated in ovarian cancer. No responses were seen in patients with refractory colorectal carcinoma or non-small cell lung cancer\textsuperscript{75,80–82}. Low response and relatively high toxicity have been found also in Phase II treatment of gastric carcinoma\textsuperscript{83}.

The antitumor activity of 2-carboxyethylgermsesquioxane (Ge-132) and its derivatives has been studied. 2-Carboxyethylgermsesquioxane has been revealed to possess antitumor\textsuperscript{2–4,11,84}, interferon-inducing\textsuperscript{4,11,85–87}, immunomodulating\textsuperscript{4,88–94} and antiviral\textsuperscript{4,95} properties. Japanese scientists first discovered antitumor activity of (O\textsubscript{1.5}GeCH\textsubscript{2}CH\textsubscript{2}COOH)\textsubscript{n} and (O\textsubscript{1.5}GeCH\textsubscript{2}CH\textsubscript{2}CONH\textsubscript{2})\textsubscript{2}.\textsuperscript{3} Mouse with Ehrlich ascite tumor received 20 µg ml\textsuperscript{-1} (O\textsubscript{1.5}GeCH\textsubscript{2}CH\textsubscript{2}COOH)\textsubscript{n} and 20 and 40 µg ml\textsuperscript{-1} (O\textsubscript{1.5}GeCH\textsubscript{2}CH\textsubscript{2}CONH\textsubscript{2})\textsubscript{n} during 7 days. The inhibition of the tumor cells growth was higher than in control by 25.9, 46.85 and 31.45%, respectively. 2-Carboxyethylgermsesquioxane exhibited some antitumor activity in adenocarcinoma LA-795, in the Lewis lung carcinoma 3LL\textsuperscript{96–99}, melanoma B16\textsuperscript{100} and leukaemia L-1210\textsuperscript{101} and had a limited antimetastatic effect in mice\textsuperscript{97}. Complete remission of pulmonary spindle cell carcinoma has been observed after oral administration of germanium sesquioxide\textsuperscript{102}. In some cases 2-carboxyethylgermsesquioxane reinforces the effect of bleomycine and 5-fluourouacil (5-FU)\textsuperscript{103}. It has been shown that (O\textsubscript{1.5}GeCH\textsubscript{2}CH\textsubscript{2}COOH)\textsubscript{n}\textsuperscript{104,105}, (O\textsubscript{1.5}GeCH\textsubscript{2}CH\textsubscript{2}COONa)\textsubscript{n}\textsuperscript{96} and (O\textsubscript{1.5}GeCH\textsubscript{2}CH\textsubscript{2}CONH\textsubscript{2})\textsubscript{n}\textsuperscript{106} prolong the life of a mouse with implanted ascitic hepatomas AH-44 and AH-66 and also of rats with syngenic bladder carcinoma BC47\textsuperscript{107}.

2-Carboxyethylgermsesquioxane was not cytotoxic to carcinoma cells growing in vitro\textsuperscript{97} and had its antitumor effect via the stimulation of host-mediated, immunopotentiating mechanisms\textsuperscript{9,97,108}, leading to augmentation of natural killer cell activity and activation of macrophages in mice\textsuperscript{97}. Carboxyethylgermaniumsesquioxane (Ge-132, 600 mg kg\textsuperscript{-1}) has some preventive effect on the precancerous lesion in rat glandular stomach induced by N-methyl-N’-nitrosoguanidine\textsuperscript{109}. A histopathological study has demonstrated that propagermanium had no biochemical influence on the renal function of renal injured (by adriamycin or mercuric chloride) rats. This confirms that propagermanium is a safe compound for use in individuals with compromised kidneys\textsuperscript{38}. The Ge-132 administered p.o. activated mouse murine macrophage-mediated tumor cytotoxicity. When Ge-132 activated macrophages have been treated with ganglioside in vitro, synergistic activity appeared\textsuperscript{110}. 2-Carboxyethylgermsesquioxane, 2-carbamoyethylgermsesquioxane and α,β-dicarboxyethylgermsesquioxane significantly stimulated mouse peritoneal macrophages and human monocytoïd cells by oral administration of a single dose of 100 mg kg\textsuperscript{-1}\textsuperscript{111}.

Antitumor activity of various organogermanium sesquioxanes [(O\textsubscript{1.5}GeCH\textsubscript{2}CHRCOX)\textsubscript{n}, R=H, Me; X=OH, NH\textsubscript{2}]\textsuperscript{100} and sesquisulfides\textsuperscript{112} has been studied. The most active was a methacrylic acid derivative (80% life prolongation in melanoma B16 and 72% life prolongation in mice with Lewis lung carcinoma).

The sesquioxanes (O\textsubscript{1.5}GeCH\textsubscript{2}CHRCOX)\textsubscript{n}\textsuperscript{113,114} and (4-RC\textsubscript{6}H\textsubscript{4}GeO\textsubscript{1.5})\textsubscript{n} (R=Hal, CN)\textsubscript{115–117} exhibited antitumor activity and prolonged the life of animals with Ehrlich ascite tumor.

Organogermanium sesquioxanes containing uracil or 5-fluourouracil (5-FU) moieties possess antitumor activity against IMC carcinoma in mice\textsuperscript{118,119}. 1-[p-[Bis(β-chloroethylamino)phenyl]-2-amino-2-carboxyethylgermanium sesquioxane (LD\textsubscript{50} 1765 mg kg\textsuperscript{-1})
inhibited the growth of sarcoma S-180 by 78% (in mice, i.p.), whereas a 65% inhibition was achieved with 5-FU under the same experimental conditions. Some germanyl heterocyclic (indolyl or furyl) amino acid derivatives, such as 1-(3′-indolyl)-2-amino-2-carboxyethylgermaniumsesquioxane and the corresponding sesquisulfide, have antitumor activity comparable with 5-FU in sarcoma S-180.

The results of bioassay showed that the organogermanium sesquioxanes containing the α-aminophosphonate group $O_1^5 GeCHR'(CHR)C(O)NHCH(R)P(O)(OPh)_2$ exhibit anticancer activity in vitro.

Preliminary pharmacological investigations of 2-(2-germaoxa-3H-benzofuran-3-yl)-2-acetylaminoglycine and 1-(2-hydroxyphenyl)-2-amino-2-carboxyethylgermanium sesquioxane showed that the sesquioxane derivative has low toxicity ($LD_{50} > 10 \text{ g/kg}$ for mice) and inhibited the growth of S-180 in mice by 51.6% (orally). The activity of this compound was slightly higher than that of 5-fluorouracil under the same experimental conditions.

Glucopyranosyl derivatives of carboxyethylgermanium sesquioxane, such as 2,4-di($O$-acetyl)-1,3,6-tri-$O$-(carboxyethyl)germanyl-$β$-D-glucopyranose, showed EEAC growth inhibition in mice (i.p.) by 62%.

Besides spirogermanium and germanium sesquioxanes, numerous other organogermanium compounds have shown antitumor activity against experimental tumors. They include the octahedral complex dimethyl-5,19,15,20-tetra-bis[3′,5′-bis(1′,1′′-dimethyl-ethylphenyl)]porphynato-germanium(IV) and some decaphenylgermanocene derivatives. 1,1-Bis(1,3-dithian-2-yl)-1-germa-3-cyclopentene has been reported to be more potent against IMC carcinoma in mice than 2-carboxyethylgermanium sesquioxane.

5-Trimethylgermyluracil and 1-(2-tetrahydrofurfuryl)-5-trimethylgermyluracil display similar cytotoxicity to melanoma B16 cells ($EC_{50}$ 32 $\mu$ g ml$^{-1}$). Preliminary biological investigations of 1-(2-tetrahydrofurfuryl)-5-fluoro-6-trimethyl(ethyl)-germyluracils have demonstrated that both derivatives inhibit the DNA and RNA biosynthesis in Frhk cells by 1.5–2 times more than Fltorafur, the well-known antitumor agent.

1-(5-Nitrofurylacryloyl)-5-trimethylgermyluracil suppresses the growth of melanoma B16 ($EC_{50}$ 10 $\mu$ g ml$^{-1}$). This compound is three times more active than its silicon analogue.

5-Trimethylgermyl derivatives of 2′-deoxyuridine exhibit antimetabolic properties: the $β$-anomer possesses weak biological action, the $α$-anomers inhibits the replication of herpes simplex virus HSV-1 and fails to display antitumor action in vivo. The $α$-anomer of 5-Trimethylgermyl-2′-deoxyuridine suppresses the incorporation of 2′-deoxyuridine and thymidine into the DNA of hepatoma 22A cells in vitro more effectively (by 88 and 27%) than the $β$-anomer (50 and 0%, respectively).

Carbofunctional organogermanium derivatives of $sym$-triazine exhibit immunodepressant properties. 1,3-Bis[γ-(triethylgermyl)propyl]-5-β-cyanoethyl-2,4,6-trioxo-1,3,5-triazine decreases the number of tumocytes 1.6-fold and significantly inhibits the growth of Sarcoma 45 in white mice.

Germanium and silicon derivatives of N-methyl-N-nitrosourea [RCH$_2$N(NO)CONH$_2$, R = Me$_2$Ge, Me$_2$PhGe, Me$_3$Si, Me$_2$PhSi, Me$_3$C] exhibit considerably higher cytotoxicity to leukaemia L1210 cells than the carbon analogue. One can suppose that it is determined by their greater lipophilicity. Dimethylphenyl derivatives are significantly more cytotoxic due either to their increased lipophilicity or to the splitting of the phenyl group.
Some trimethylgermyl and trimethylsilyl derivatives of retinobenzoic acids show high retinoidal activity in human promyelocytic leukaemia cells HL-60\(^\text{135}\).

Antitumor activity of germyl derivatives of hetaryldiketones have been tested on HT-1080 and MG-22A tumor cell cultures\(^\text{46,136}\). 2,2-Dimethyl-5-(5′-trimethylgermyl-2′-furfurylidene)-1,3-dioxane-4,6-dione and 2,2-dimethyl-5-(5′-trimethylgermyl-2′-thienylidene)-1,3-dioxane-4,6-dione (IC\(_{50}\) ca 100 µg ml\(^{-1}\)) have low influence on the HT-1080 cell line but the cytotoxicity considerably increases in MG-22A cells (IC\(_{50}\) 1–10 µg ml\(^{-1}\)).

1-Triphenylgermyl-4-propiono-substituted semicarbazides, thiosemicarbazides \(\text{Ph}_3\text{GeCH}_2\text{CONHCH}(\text{X})\text{NHR}^{\text{R′}}\) (\(\text{R′} = \text{H, Ph; R″} = \text{Ph, p-tolyl; X} = \text{O, S}\)) and their heterocyclic derivatives have been found to possess inhibitory effects on gastric carcinoma MGC-803 \textit{in vitro}\(^\text{137}\).

Germanium and silicon derivatives of furfural semicarbazone and thiosemicarbazone exhibited similar antitumor activity to melanoma B16 in mice (40–48% inhibition of the growth)\(^\text{138}\).

The germanium derivative of furfural oxime had significant activity on HT-1080, MG-22A and B16 cells, but not on Neuro 2A. The activity of carbon and silicon analogues was lower in all cell lines (Table 18)\(^\text{139}\).

\(t\)-Butyl \(\alpha\)-cyano-(5-trimethylgermyl-2-furyl)acrylate possesses significant cytotoxicity on four (HT-1080, MG-22A, B16, Neuro 2A) tumor cell lines and it is a strong NO-inducer\(^\text{46}\). However, the silicon analogue was more active in 3 cell lines (Table 19).

2-(5′-Triethylgermyl-3′-oxazolinyl)pyridine hydrochloride, 2-(5′-triethylgermylmethyl-3′-oxazolinyl)pyridine hydrochloride, (3-methyl-4-triphenylgermylisoaxazolinyl-2)-5-carboxylic acid ethyl ester and (3-ethyl-4-triphenylgermylisoaxazolinyl-2)-5-carboxylic acid ethyl ester had medium activity on HT-1080 and MG-22A tumor cell cultures, and low activity on B16. The most active antitumor substance was (3-ethyl-4-triphenylgermylisoaxazolinyl-2)-5-carboxylic acid ethyl ester. Germlyisoaxazolin-2-yl derivatives are stronger tumor growth inhibitors and NO-inducers than their silyl analogues\(^\text{44}\). Cytotoxic activity of germyl-substituted 4,4-dioxo-3a,6a-dihydrothieno[2,3-d]isoaxazolines-2 has been studied\(^\text{140}\). Germanium-containing compounds had a cytotoxic effect on Neuro 2A and B16 cell lines. 4,4-Dioxo-3-phenyl-5-trimethylgermyl-3a,6a-dihydrothieno[2,3-d]isoaxazoline-2 showed the highest tumor growth inhibiting activity.

\(^a\)CV = Crystal Violet.

\(^b\)MTT = 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide.

\(^c\)Not active.
The antitumor activity of two types of gematrane, RGe(OCH₂CH₂)₃N and R₃MOGe(OCH₂CH₂)₃N (R = alkyl, aryl, furyl, thienyl, phenyl; M = Si, Ge), has been studied. The gematrane R₃MOGe(OCH₂CH₂)₃N possess higher activity on HT-1080, MG-22A, B16 and Neuro 2A tumor cells (IC₅₀ 0.9–6.1 µg ml⁻¹) than RGe(OCH₂CH₂)₃N (IC₅₀ ca 100 µg ml⁻¹). Hydroxygermatrane had the highest cytotoxic activity on HT-1080 tumor cells. 1-Trimethylgermoxygermatrane (EC₅₀ 3.2 µg ml⁻¹) suppressed the growth of melanoma B16 cells three times more effectively than 1-trimethylsiloxygermatrane (EC₅₀ 10 µg ml⁻¹). 1-Trimethylsiloxy- and 1-trimethylgermoxy gematrane inhibited the growth of Sarcoma 37 in mice more effectively than the parent 1-hydroxygermatrane (by 75, 60 and 40% respectively). Administration of 3-(1-germatranyl)propionic acid to mice afflicted with Ehrlich ascites tumor caused a 78% increase in survival time. Germatrane-N(CH₂CH₂O)₃Ge(CHR)₂CONH₂ (R = H, Ph) showed activity against IMC carcinoma in mice.

Some alkyldigermanes possess antitumor activity against leukaemia L-1210 in vitro. Further investigations in vivo have demonstrated that these compounds possess low activity and exhibit antitumor activity only against leukaemia P-388.

Water-soluble derivatives of n-Bu₂Sn(O₂CCHR₁CHR₂GeR₃)₂·H₂O [type I: R¹ = H; R² = H, CH₃, C₆H₅, 4-ClC₆H₄, 2-CIC₆H₄, 4-CH₃C₆H₄, 2-CH₃C₆H₄, 2,4-Cl₂C₆H₃, 4-CH₃OC₆H₄; R³ = (OCH₂CH₂)₃N; type II: R¹ = H; R² = CH₃, C₆H₅, 4-ClC₆H₄, 4-CH₃C₆H₄, 4-CH₃OC₆H₄; R³ = Ph₃] were screened in vitro for their antitumor activity against KB cells, HCT-8 cells and Bel7402. All compounds showed some activity. The gematrane-substituted derivatives were more active than the GePh₃-substituted derivatives.

The effects of propagermanium on various virus-infected mice were investigated. Oral administration of propagermanium in mice infected with herpes simplex virus type I (HSV-1) significantly prolonged the mean survival time. In vaccinia virus-infected mice (oral doses 0.2–10 mg kg⁻¹) it suppressed the number of pocks on the tail which were induced by the virus. Propagermanium (0.5–10 mg kg⁻¹), given orally to HSV-1-infected mice, induced cytotoxic T lymphocytes against HSV-1 antigen. In addition, propagermanium (1–10 mg kg⁻¹) enhanced interferon-γ (IFN-γ) induction in mice treated with Mycobacterium bovis. In mice spleen cell cultured with Concanavalin A, 0.1–10 mg ml⁻¹ of propagermanium stimulated interleukin 2 production. It seems likely that the antiviral activity of propagermanium was exerted via enhancement of host immune resistance against viral infection. Propagermanium improves hepatitis.
through mechanisms including the reduced production of tumor necrosis factor without modification of Th-1 and Th-2 cell function\textsuperscript{147}.

Investigations of new biological applications of Ge-132 are presently proceeding in Japan. For example, a biologically active composition for treatment of acquired immune deficiency syndrome and cancer has been prepared by extraction maitake (mushroom) with solvents and mixing the extract containing D fraction and glucan with organogermainium sesquioxane [(GeCH\(_2\)CH\(_2\)COOH)\(_2\)O\(_3\)]\textsuperscript{148}. A composition of Ge-132 (>10%) and mushroom extracts (>70%) have been claimed to increase therapeutic efficacy and decrease toxicity and side effects of antiviral agent (e.g. HIV reverse transcriptase inhibition) against the AIDS virus\textsuperscript{149}. Foods containing fucoidan, polysaccharides and (GeCH\(_2\)CH\(_2\)COOH)\(_2\)O\(_3\) showed synergistic anticancer activity\textsuperscript{150}. Activated water containing ferrous ferric salts and Ge-132 showed natural killer activity enhancement of volunteers\textsuperscript{151,152}.

The effects of the synthetic germanium antioxidant (Ge-132) have been studied on liver oxidative damage induced by pararquat in senescence-accelerated mice. Pararquat administered intravenously to SAM-P/8 (susceptible) or SAM-R/1 (resistant) mice increased liver DNA strand breakage and malondialdehyde levels, which are indicators of oxidant damage. Ge-132 effectively blocked pararquat-induced effects on liver DNA strand breaks and malondialdehyde levels. In addition, Ge-132 significantly elevated the activities of hepatic superoxide dismutase and catalase following pararquat pretreatment. Histopathologically, Ge-132 inhibited pararquat-induced hepatic mitochondrial injury in both strains, but more effectively in the susceptible strain. The data suggest that Ge-132 may be useful as an antioxidant in view of its ability to prevent pararquat-induced hepatic oxidant injury\textsuperscript{153}. Ge-132 has a cell membrane stabilizing effect\textsuperscript{154}.

Some plants have been cultivated by germanium penetration into the plant from its roots and organogermainium pharmaceuticals have been prepared\textsuperscript{155}. Cultivation of Saccharomyces cerevisiae or Ganoderma lucidum in carboxyethylgermanium sesquioxane medium gave a product with antitumor and interferon-inducing activity\textsuperscript{156}.

\section*{VI. RADIOPROTective ACTIVITY}

The radioprotective activity of several classes of organogermainium derivatives (germatiazolines, germadithioacets, germaranes and germylated sulfides) has been studied\textsuperscript{41,43,157–159}.

The radiation (\textsuperscript{60}Co \(\gamma\)-ray source) protection was obtained in mice after \textit{i.p.} administration of germainiazolines. Generally, these organogermainium compounds have a lower toxicity and a radioprotective activity equal to or greater than that of the starting organic derivatives (Table 20). It is necessary to underline that in some cases this increased radioprotective activity was obtained with organogermainylated or organosilylated derivatives injected in lower doses than those used for the parent organic compounds\textsuperscript{42,43,159}.

Germadithioacetals R\(^1\)R\(^2\)Ge[SCH(R\(^3\))CH\(_2\)R\(^4\)]\(_2\) have an important radioprotective activity (DRF 1.5–1.7)\textsuperscript{42,43,159–162}.

Four aminoalkylthio germaranes YNHCH\(_2\)CH(R)S-Ge[(OCH\(_2\)CH\(_2\))]\(_3\)N; R = H, Me, Y = H · HCl, H\(_2\)N(CH\(_2\))\(_3\), 2HCl · H\(_2\)N(CH\(_2\))\(_3\) have been tested as radioprotective agents\textsuperscript{157}. They demonstrated low toxicity (LD\(_{50}\) 300–1500 mg kg\(^{-1}\)) and medium radioprotective activity (DRF 1.4–1.5). Similar radioprotective potency has been found for derivatives of cysteamine, with its sulfur atom being bound with silatrane or germatrane groups, as well as for their thia analogues H\(_2\)N(CH\(_2\))\(_2\)SM(XCH\(_2\)CH\(_2\))\(_3\)N (M = Si, Ge; X = O, S)\textsuperscript{158}.

Germylated sulfides [(HCl · H\(_2\)NCH\(_2\)CH\(_2\)S\(_2\))GeS\(_3\)]\(_3\)\textsuperscript{157} and [(HCl · H\(_2\)NCHMeCH\(_2\)S\(_2\)GeS\(_3\)]\(_3\)\textsuperscript{159} have significant radioprotective activity (DRF >1.5, LD\(_{50}\) 800 mg kg\(^{-1}\) and DRF 1.6, LD\(_{50}\) 1000 mg kg\(^{-1}\), respectively).
TABLE 20. Radioprotective activity of \( \text{Ge} \)

VII. MISCELLANEOUS ACTIVITIES

The germanium analogue of the leading agricultural fungicide flusilazole has been synthesized\(^{163}\). The fungicidal properties of flusilazole and of bis(4-fluorophenyl)methyl(1\(H\)-1, 2,4-triazol-1-yl methyl)germane have been compared and found to be similar. Dose-

dependent fungicidal activity has been demonstrated for the germanium derivative of \textit{o-chlorobenzamide} (Table 21)\textsuperscript{164}.

Antimutagenic activity of bis(D,L-lactato)-, bis(L-lactato)-, bis(thiolactato)- and bis (thioglycolato)germanium(IV) has been tested in \textit{Salmonella typhimurium} strains TA98 and TA100. They showed moderate activity against the mutagenic effect of nitroaromatic compounds\textsuperscript{165}.

Spirogermanium has antimalarial activity\textsuperscript{9}, but had no effect on \textit{Babesia microti} infection in the hamster model\textsuperscript{166}.

2-Carboxyethylgermsesquioxane can inhibit bone resorption by osteoclasts in a concentration-dependent manner\textsuperscript{167}. The therapeutic effect of 2-carboxyethylgermanium sesquioxide (Ge-132) for experimental osteoporosis has been studied using ovariectomized rats maintained on a low calcium containing diet. The Ge-132 decreased the bone strength, and affected the femur cortical bone index and bone mineral mass caused by osteoporosis\textsuperscript{168}.

The non-enzymic glycosylation (Maillard reaction) of amino acids with glucose has been markedly suppressed in the presence of Ge-132 in the range of 1–10 mmol l\textsuperscript{-1}. These results demonstrated antidiabetic properties of Ge-132\textsuperscript{169}. Some derivatives of carboxyethylgermsesquioxane also inhibited the Maillard reaction\textsuperscript{170,171}. As protein modification, such as glycation, may play a role in initiating changes that lead to cataract development, the effect of Ge-132 on galactose-induced cataractogenesis has been studied. It has been found that Ge-132 acted as antiglycation agent and delayed cataract formation. This compound was effective in maintaining Na(+)-K(+) -ATPase\textsuperscript{172,173}.

The interaction of carbonic anhydrase (CA) isozymes I and II with a series of organogermanium derivatives such as Mes\textsubscript{3}GeOH, Mes\textsubscript{3}GeNH\textsubscript{2}\textsuperscript{174} and aryl-substituted sulfonamides RR'RR''GeNSO\textsubscript{2}GeC\textsubscript{6}H\textsubscript{4}X-p (R = R' = Mes (mesityl), R'' = Cl, X = Me; R = R' = R'' = Ph, X = Me, NH\textsubscript{2}; R = R' = R'' = Et, X = Me), Mes\textsubscript{2}Ge=NSO\textsubscript{2}C\textsubscript{6}H\textsubscript{4}Me-p, Mes\textsubscript{2}Ge(NHSO\textsubscript{2}C\textsubscript{6}H\textsubscript{4}Me-p)\textsubscript{2} has been studied\textsuperscript{175}. The germanols and germylamine demonstrated selective inhibition of CA II. Sulfonamides were active in inhibiting both isozymes, the ethyl derivative being the most active CA II inhibitor in this series of compounds.

The first germanium-containing decapeptide \[\text{Ac-D-Nal}^1-4-\text{Cl-D-Phe}^2-\text{D-Pal}^3-\text{Ser}^4-\text{Me}_{3}\text{GeAla-D-Cit}^6-\text{Leu}^7-\text{Arg}^8-\text{Pro}^9-\text{D-Ala}^{10}-\text{NH}_2; \text{Me}_3\text{GeAla} = \text{Me}_3\text{GeCH}_2\text{CH(\text{NH}_2) COOH}] has been studied \textit{in vitro} in receptor binding and functional assays using recombinant cell lines expressing the human gonadotropin-releasing hormone (GnRH) receptor\textsuperscript{60,176}. This decapeptide like its silicon and carbon analogues behaved as potent GnRH antagonist,
the binding affinities and antagonistic potencies of the three analogues being quite similar. The investigation in vivo in the male rat after s.c. administration demonstrated that they produced both a strong testosterone suppression (single-dose treatment 1.5 mg kg$^{-1}$) and a strong luteinizing hormone (LH) suppression (castrated male rat; single-dose treatment, 0.05 mg kg$^{-1}$). For germanium and silicon-containing decapeptides, the testosterone and LH suppression lasted for a significantly longer period of time compared with the effects of the carbon analogue.

I. TIN

A. Introduction

Organotin compounds (OTCs) are extensively used in a variety of industrial processes as catalysts and stabilizers for polyvinyl chloride plastics. The biological interest in this class of compounds for agriculture is due to high fungicidal, bactericidal and insecticidal activity. They were also incorporated into paints applied as antifouling agents on fishing nets and on boat hulls and used as preservatives for wood, textiles, paper, leather and electrical equipment. Recently, different di- and triorganotin carboxylates were investigated for antitumor activity. The increasing environmental pollution by the organotin derivatives has become a serious problem for various ecosystems, including humans. Due to this fact the toxic effects of OTCs have been widely explored and general trends in toxicity and biological activity were reviewed. 

B. Toxicity

Organotin derivatives exhibit genotoxic, neurotoxic, immunotoxic and hepatotoxic effects. It is important to study the genotoxicity of tin compounds, as they have the
potency to induce mutations and cancer. The genotoxicity of various methyl-, butyl- and phenyltins as well as tetrachlorostannane was studied in the SOS chromotest and rec-assay with *Escherichia coli* PQ37 and *Bacillus subtilis*. Organotin chlorides Me₃SnCl, Me₂SnCl₂, Bu₃SnCl, Bu₂SnCl₂ and bis(tributyltin)oxide (Bu₃Sn)₂O were recognized as genotoxic chemicals by the rec-assay, they damaged DNA in *Bacillus subtilis*, were SOS inducers in *Escherichia coli* PQ37 strain⁷ and were mutagens in *Salmonella typhimurium* TA100 and TA98 strains by an induced mutation frequency test⁸. However, when isolated λ-DNA was incubated with MeSnCl₃, Me₂SnCl₂, Me₃SnCl, BuSnCl₃ and Bu₂SnCl₂ in reaction systems both with and without hydrogen peroxide, the DNA breakage was not observed. Bivalent (SnCl₂) and tetravalent (SnCl₄) tin chlorides caused DNA breakage in the presence of hydrogen peroxide. The DNA damage activity for the bivalent compound was much more potent than for the tetravalent one⁹. Submicromolecular concentrations of tributyltin derivatives were found to induce the expression of several stress proteins, most notably HSP89 and HSP70, in IMR-90 human diploid fibroblasts in a time- and dose-dependent manner¹⁰.

Triphenyltin acetate and triphenyltin hydroxide were evaluated to induce micronuclei and sister chromatid exchange *in vitro* using cultured Chinese hamster ovary cells and *in vivo* on BALB/c mouse erythrocytes. This study demonstrated that both compounds are potential chromosome mutagens¹¹. Genotoxicity testing was performed for Et₂SnCl₂·L [L = N-(2-pyridylmethylene)-4-toluidine] complex in mouse bone-marrow cells *in vivo*. This compound induced delay in cell-cycle kinetics and significant sister chromatid changes¹². An increasing effect of different tributyl- and triphenyltins on the frequency of chemically induced breaking-type chromatid aberrations in cultured Chinese hamster ovary cells was observed¹³.

The chromosome abnormalities caused by different chlorostannanes and their complexes and occurring during both mitotic and meiotic processes have been studied *in vitro* on V79 Chinese hamster cells¹⁴ and *in vivo* on mitotic chromosomes of *Rutilus rubilio* (Pisces, Cyprinidae)¹⁵, gill tissue of *Aphanius Fasciatus* (Pisces, Cyprinodontiformes)¹⁶, male gonads of *Truncatella subcyllindrica* (Mollusca, Mesogastropoda)¹⁷ and *Ciona intestinales* fertilized eggs at different stages of development¹⁸.

The frequency of micronuclei induced by mitomycin C in mouse peripheral reticulocytes was enhanced by treatment with bis(tributyltin) oxide and triphenyltin chloride. These compounds did not themselves induce micronucleated reticulocytes (MNRET); however, 50 mg kg⁻¹ of (Bu₃Sn)₂O or 100 mg kg⁻¹ Ph₃SnCl given orally to mice, simultaneously with an intraperitoneal administration of mitomycin C (1 mg kg⁻¹), caused about 55% and 51% increases of MNRET frequency. These data demonstrate that OTCs act as coclastogens in a whole mammalian system¹⁹.

A synergistic effect of 2,3,3′,4,4′-pentachlorobiphenyl with triphenyltin derivatives in induction of the aberrant mitosis was detected. Inactive concentrations of both agents caused abnormal configurations when combined²⁰.

OTCs have severe effects on the immune systems, causing premature atrophy of thymus gland and lymphoid tissues as well as inhibition of spleen cell activity. Inhibition of phagocytosis and cytolyis of polymorphonuclear leukocytes with resultant depression of cell-mediated immune responses have also been demonstrated²¹–³⁷. The influence of the thymus atrophy-inducing dibutyltin dichloride Bu₂SnCl₂ on the differentiation and proliferation of immature rat thymocyte subsets were studied *in vivo* and *in vitro*. The atrophy results from a depletion of small CD4+CD8+ thymocytes which is caused by a diminished production of immature CD4+CD8+ and CD4+CD8+ thymoblasts. Dibutyltin dichloride inhibits the activation, but not the differentiation of immature CD4+CD8+ thymocytes *in vivo* and *in vitro*, suggesting a selective antiproliferative activity of this compound. It also
inhibits the adhesion molecule-mediated binding of thymocytes to thymic epithelial cells and enhances the \( \text{Ca}^{2+} \) release elicited by cross-linking of the T cell receptor complex on thymocytes. It may be concluded that dibutyltin dichloride possibly interferes with the functioning of the cytoskeleton\(^{21–26}\).

As organotin derivatives are the most harmful compounds of coastal pollutants, their immunotoxic effects were studied in aquatic organisms such as channel catfish \( \text{Ictalurus punctatus} \)^{33}, cultivated clam \( \text{Tapes philippinarum} \)^{36}, tunicates \( \text{Botryllus schlosseri} \)^{34,35} and \( \text{Ciona intestinalis} \)^{37}. Single intraperitoneal injections of corn oil with 0, 0.01, 0.1 and 1.0 mg kg\(^{-1} \) of tributyltin chloride were given to channel catfish. Three and seven days later, non-specific cytotoxic cell functions and humoral blood response were evaluated for allometric indices and hematology. Peripheral blood neutrophilia and specific antibody secreting cell numbers were the most sensitive parameters and were affected in all concentration groups. Allometric indices, peripheral blood lymphocyte and monocyte percentages, non-specific cytotoxic cell functions and phagocyte oxidative burst were less sensitive and were affected only at the higher dose of tributyltin chloride\(^{33}\).

Phagocytosis of yeast \textit{cells in vitro} by \( \text{Botryllus schlosseri} \) hemocytes is negatively affected by organotins present in the incubation medium. \( \text{Bu}_3\text{SnCl}, \text{Bu}_2\text{SnCl}_2 \) and \( \text{BuSnCl}_3 \) significantly reduce the phagocytic index, which ranges between 12 and 15 in controls, at a concentration of 10 \( \mu \text{M} \); \( \text{Bu}_3\text{SnCl} \) and \( \text{Bu}_2\text{SnCl}_2 \) significantly inhibit at 1 \( \mu \text{M} \) also, \( \text{Bu}_2\text{SnCl}_2 \) being more effective than \( \text{Bu}_3\text{SnCl} \)^{34}. After 1 h of \( \text{Botryllus schlosseri} \) hemocytes exposure to tributyltin chloride, nuclear changes, i.e. significant collapse and cleavage of chromatin, were observed. Hemocyte mortality increased significantly only after 2 h. All these apoptotic events may be closely related to cytosolic calcium increase resulting in activation of endonucleases\(^{35}\).

The effects of different OTC in human immune tissue were studied in isolated tonsil B cells. Non-stimulated B cells were killed by 100 nM concentration of all tested OTC after 8 h \textit{in vitro} culture. Organotin derivatives also decreased the proliferation of tonsillar B lymphocytes stimulated with \( \text{Staphylococcus aureus} \) Cowan 1 and IL-2, when present at 100 nM and higher concentrations. Increased phosphatidylserine exposure demonstrated that 100 nM concentration of triphenyltin chloride and dibutyltin dichloride induced B cells to die by apoptosis\(^{38}\).

The histopathological examination of the human thymus grafts of SCID-hu mice (SCID mice engrafted with human fetal thymus) exposed to dibutyltin dichloride showed a reduction in the relative size of the thymus cortex, an effect also described in rodents. These results indicate that the human thymus is a target for immunotoxic action of organotins\(^{27}\).

OTCs have toxic effects on the central nervous system. The neurotoxicity of trimethyltin derivatives was investigated widely\(^{39–41}\). Organotin exposure culminates in its accumulations in the CNS and PNS; the clinical picture is dominated by neurological disturbances. Trimethyltin chloride is primarily a CNS neurotoxin affecting neurons within the hippocampal pyramidal band and the fascia dentata. The triethyltin analogue is a neurotoxin that produces a pathological picture dominated by brain and spinal cord edema\(^{39}\). Developmental neurotoxicity may be influenced by effects of OTCs on endocrine function. Thus, trimethyltin hydroxide increases the corticosterone response to stress in developing rat pups (Long-Evans rat pups were injected i.p. with either 6 mg kg\(^{-1} \) \( \text{Me}_3\text{SnOH} \) in 10 \( \mu \text{l} \) \( \text{kg}^{-1} \) BW NaCl or vehicle on postnatal day 5 or 10)^{40}. Tributyltin and triphenyltin acetates produced significant central nervous system and respiratory depressions at single doses of 200 and 300 mg kg\(^{-1} \), respectively (the median lethal doses were 297.54 and 402.38 mg kg\(^{-1} \), p.o.). The histopathological findings showed pulmonary, hepatic and renal congestion, brain hemorrhages and destruction of the intestinal mucosa\(^{32}\).
The gliotoxicity of different organotins was investigated\textsuperscript{43,44}. The exposure of C6 glioma cells\textsuperscript{43} to OTCs at subtoxic concentrations for 24 h increased the amount of reduced glutathione (GSH). Increases of glutathione-S-transferase enzyme activity were also demonstrated after organotin exposure. This suggests that glutathione increases occur in glial cells after toxic insults, possibly acting as a protective mechanism. To test whether GSH plays a role in organotin-induced cell death, the effect of GSH addition in the culture media or via intracellular increase was studied. The GSH addition to the culture media did not protect the cells. However, pre-treatment with (-)-2-oxo-4-thiazolidine carboxylic acid, which increases intracellular GSH level, protected the cells against organotins.

The course of pancreatic fibrosis in rats induced by dibutyltin dichloride was studied 2–36 weeks after single i.v. treatment of rats with dose of 6 or 8 mg kg\textsuperscript{-1}. The pancreatic fibrosis induced by Bu\textsubscript{2}SnCl\textsubscript{2} differs from other experimental models of acute pancreatitis. Extensive infiltration is present in fibrotic areas without pancreatic atrophy or lipomatosis. The presence of chronic inflammatory lesions characterized by the destruction of exocrine parenchyma and fibrosis, and in the later stages the endocrine parenchyma, indicates a chronic pancreatitis\textsuperscript{45}.

Assessment of the relative teratogenic potential of triphenyltin chloride, trimethyltin chloride, triethyltin bromide, bis(tributyltin) oxide, tributyltin chloride and its metabolites, i.e. (3-hydroxybutyl)dibutyltin chloride, dibutyltin dichloride and butyltin trichloride, have been conducted using rat embryo limb bud cell cultures (LBC) to gain some knowledge of OTC’s embryotoxicity and teratogenicity\textsuperscript{46}. Fifty-percent inhibition concentration for cell proliferation (IP\textsubscript{50}) and for cell differentiation (ID\textsubscript{50}) and the ratio of the former to the latter (P/D ratio) were obtained. The ID\textsubscript{50} values increased in the following order of compounds: Ph\textsubscript{3}SnCl, Bu\textsubscript{2}SnCl\textsubscript{2} < Bu\textsubscript{3}SnCl, (Bu\textsubscript{3}Sn)\textsubscript{2}O < MeCH(OH)CH\textsubscript{2}CH\textsubscript{2}SnBu\textsubscript{2}Cl < Et\textsubscript{3}SnBr < Me\textsubscript{3}SnCl ≪ BuSnCl\textsubscript{3}. With the exception of BuSnCl\textsubscript{3}, the organotin compounds tested were very strong inhibitors of cell differentiation (ID\textsubscript{50} = 0.13–1.71 µM) and cell proliferation (IP\textsubscript{50} = 0.12–2.81 µM). P/D ratios for Bu\textsubscript{3}SnCl, MeCH(OH)CH\textsubscript{2}CH\textsubscript{2}SnBu\textsubscript{2}Cl, Bu\textsubscript{2}SnCl\textsubscript{2} and BuSnCl\textsubscript{3} were 1.0, 1.43, 1.32 and 1.08, respectively. The results suggest that tributyltin chloride is rather embryocidal than teratogenic.

The hemolytic effects of different organotin compounds were studied with white rabbit erythrocytes. Tributyltin chloride showed the highest hemolytic activity (EC\textsubscript{50} = 7.48 µM) and the hemolysis by this compound proceeded rapidly. Methyltin derivatives are less toxic (EC\textsubscript{50} = 364 µM). No significant difference in hemolytic activity based on divergences of the anionic functional group X in R\textsubscript{3}SnX (X = F, Cl, Br, OH, OMe, OEt, OAc) was observed\textsuperscript{47}. Various cations (Zn\textsuperscript{2+}, Co\textsuperscript{2+}, Cd\textsuperscript{2+} in a concentration of 50 µM) totally protect the erythrocytes against hemolysis induced by Pr\textsubscript{3}SnCl. The monovalent K\textsuperscript{+} and (C\textsubscript{12}H\textsubscript{25})Me\textsubscript{3}N\textsuperscript{+} ions are less potent inhibitors of hemolysis\textsuperscript{48}.

The stability of trout hemoglobin was examined in the presence of some organotin compounds. Tributyltin and triphenyltin chlorides protect HbI from the oxidation; the same compounds accelerate precipitation process in HbIV to a great extent. Mercury p-hydroxymercuribenzoate, an agent blocking free SH-groups of the protein, abolished the ability of triphenyltin chloride to decrease the oxidation rate of HbI\textsuperscript{49}.

The \textit{in vitro} effects of triphenyltin acetate on cytochrome P450 content and functions were investigated in liver microsomes from untreated and phenobarbital- or β-naphthoflavone pretreated rats. At a concentration of 0.5 mM, Ph\textsubscript{3}SnCl caused a marked loss in the spectrally detectable content of cytochrome P450, up to 27% of its original value, along with an increase in the inactive form cytochrome P420 and acted as an almost specific and powerful \textit{in vitro} inhibitor of cytochrome P450-dependent monoxygenases, apparently through the interaction with sulfhydryl groups of the hemoprotein\textsuperscript{50}. Subchronic
(70 days) oral exposure from moderate to high levels of triphenyltin acetate would affect the microsomal hepatic and renal drug-metabolizing enzymes in rabbits and lambs. In the rabbit livers, Ph$_3$SnCl failed to affect the cytochrome P450 content or the oxidative, hydrolytic or conjugative enzyme activities. In contrast, a striking dose-related increase in both P450 content and carboxylesterase activity (up to 280%) was detected in rabbit’s kidneys.

The interaction of triphenyltin chloride with fish microsomal monooxygenase systems has been studied in vitro and in vivo in the marine fish scup (Stenotomus chrysops). In vitro incubation of fish liver microsomes with Ph$_3$SnCl resulted in the conversion of about 40% of the native total spectral P450 to P420. In addition, a strong concentration-related inhibition of ethoxyresorufin O-deethylase activity was observed, with complete loss at concentration of 1.0 mM. Further in vitro incubation showed that NADPH, but not NADH, cytochrome c reductase was strongly inhibited at 100 µM and higher. To investigate this effect further, fish were injected with single doses of 5, 25 and 50 µM Ph$_3$SnCl (1.9, 9.6 and 19.3 mg kg$^{-1}$), and 24 and 48 h later, hepatic microsomes were analyzed for total P450 content, ethoxyresorufin O-deethylase activity and NAD(P)H cytochrome c reductase. Ethoxyresorufin O-deethylase activity tended to be decreased in Ph$_3$SnCl-treated scup, with the response being stronger after 48 h than after 24 h. No significant conversion of spectrally determined P450 to cytochrome P420 was found. These data combined with previous results indicate a general degenerative effect of organotins on the fish microsomal monooxygenase system.

The biochemical mechanism through which OTCs induce cell damages remains unclear. However, it was suggested that tetracoordinate organotin compounds R$_3$SnCl (R = Bu, Ph) are potent inhibitors of the mitochondrial ATP synthase complex, all acting on the membrane sector F0 of ATP synthase. Tributyltin derivatives induced rapid (maximal by 3 min) and sustained elevation in intracellular calcium levels in Jurkat T cells. This was preceded by mitochondrial hyperpolarization with subsequent loss of membrane potential over the next 15 min. The effect of R$_3$SnCl (R = Ph, Bu, Et, Me) on intracellular Ca$^{2+}$ level and survival in PC12 cells was examined. Treatment with micromolar concentrations of tributyl and triphenyl derivatives caused a rapid increase in the cytosolic free Ca$^{2+}$ concentration. When the Ca$^{2+}$ elevation was maintained for over 30 min, internucleosomal DNA cleavage typical of apoptotic cell death followed. These data suggest that the toxicity of organotins in PC12 cells is linked to their ability to promote intracellular Ca$^{2+}$ overload, which triggers apoptosis.

Tributyltin chloride Bu$_3$SnCl and its in vitro metabolites in rat liver microsomal enzyme systems, (3-hydroxybutyl)dibutyltin chloride, (3-oxobutyl)dibutyltin chloride, Bu$_2$SnCl$_2$ and BuSnCl$_3$, were intraperitoneally administered to male rats in order to investigate sulfur-containing metabolites in the urine. Administration of (3-hydroxybutyl)dibutyltin chloride and (3-oxobutyl)dibutyltin chloride gave higher amounts of mercapturic acid derivatives, such as N-acetyl-S-(3-oxobutyl)-L-cysteine and N-acetyl-S-(3-hydroxybutyl)-L-cysteine, than Bu$_2$SnCl$_2$ and BuSnCl$_3$. On the other hand, dibutyltin dichloride and butyltin trichloride did not yield measurable amounts of N-acetyl-S-(3-oxobutyl)-L-cysteine and/or N-acetyl-S-(3-hydroxybutyl)-L-cysteine. The appearance of organotin metabolites in urine indicates that (3-hydroxybutyl)dibutyltin chloride, (3-oxobutyl)dibutyltin chloride and hypothesized secondary metabolites, such as butyl(3-hydroxybutyl)(3-oxobutyl)tin chloride, butyl(3-hydroxybutyl)(4-hydroxybutyl)tin chloride, etc., are subject to the action of glutathione S-transferase to give mercapturic acid derivatives.

Antidotal effects of 2,3-dimercaptopropane-1-sulfonic (DMPS) and meso-2,3-dimercaptosuccinic (DMSA) acids on the toxicity of dibutyltin dichloride in rats were
studied using different doses and routes of administration (i.p. and p.o.) of both chelators. Several parameters of organotoxicity (thymus weight and cellularity, bile duct diameter, histological lesions of pancreas and liver, activities of amylase, lipase and alkaline phosphatase, bilirubin and hyaluronic acid in serum) were measured from 6 h to 8 weeks. DMPS and DMSA diminished the dibutyltin dichloride induced bile duct, pancreas and liver lesions more strongly than the thymus atrophy. Moreover, the development of a fibrosis of the pancreas and cirrhosis of liver several weeks after single administration of Bu₂SnCl₂ to rats was inhibited by DMPS and DMSA⁵⁹.

Some cases of human intoxication by OTCs were reported. Three patients who developed acute nephropathy after ingestion of triphenyltin acetate Ph₃SnOAc had significant proteinurea, azotemia and polyurea. Mild neurological manifestations in all patients were also noted. Hematuria and pyuria were detected in one severely poisoned patient. Evidence for hepatitis was present in two patients, and for pancreatitis in one. Renal biopsy showed focal fusion of glomerular cell processes and proximal tubular damage with cellular necrosis. Two patients survived with complete recovery of renal functions. One old patient died of aspiration pneumonia⁶⁰. A chemistry student was acutely exposed to vapors of an organotin compound. Seventy-two hours later he exhibited delirium, spatial disorientation, perseveration, inappropriate affect and memory defects. Trimethyltin derivatives were identified in blood and urine samples taken 17 days after the accident; the level of tin in blood was elevated 35 days after exposure. Serial electroencephalograms showed memory defects, cognitive dysfunction and dysphoria four years after⁶¹.

As the elevation of tin concentrations in human blood was detected in Alzheimer’s disease, attempts to detect organotins in a human brain tissue which showed neuropathological evidence of Alzheimer’s disease were undertaken. However, OTCs with low molecular weight were not found. It is possible that tin derivatives form complexes with large organic molecules, which are not volatile for gas chromatography⁶².

C. Antimicrobial Activity

The effects of triorganotin 2-naphthylthiolates 2-C₁₀H₇SSnR₃ (R = Me, c-C₆H₁₁, PhCH₂, Ph) and diorganotin bis(2-naphthyl)thiolates (2-C₁₀H₇S)₂SnR₂ (R = Me, Bn) were tested against 10 bacteria: Salmonella typhi, Shigella boydii, Corynebacterium diphtheria, Staphylococcus pyogenes, Escherichia coli, Corynebacterium hoffmannii, Staphylococcus faecalis, Klebsiella pneumoniae, Proteus vulgaris and Staphylococcus aureus⁶³. The antibacterial activity is maximal for the tributyl compound 2-C₁₀H₇SSnBu₃ (MIC < 100–150 µg ml⁻¹), whereas the tricyclohexyl derivative 2-C₁₀H₇SSn(C₆H₁₁-c)₃ was inactive.

The results of antimicrobial action in vitro of Ph₂SnCl₂, Bu₂SnO and their complexes R₂SnL (L = dianion of alanylatedalanine, phenylalanylleucine, phenyalanylphenylalanine and glycoisoleucine) are presented in Table 1⁶⁴. Dibutyl complexes are found to be more active than Bu₂SnO whereas diphenyltin derivatives with some exceptions are less active than Ph₂SnCl₂. Minimum inhibitory concentration for diphenyltin complexes Ph₂SnL₂ varied in the <12.5–50 µg ml⁻¹ region (Staphylococcus faecalis, Klebsiella pneumoniae, Escherichia coli, Pseudomonas aeruginosa and Staphylococcus aureus)⁶⁵. The organotin derivatives of amino acids having nitrogen-containing heterocyclic rings, i.e. L-histidine and L,D-tryptophan, have been tested in vitro against the same bacteria. Bactericidal activity decreased in the order Ph₃SnL > Bu₂SnL₂ > Me₃SnL (HL = L,D-tryptophan)⁶⁶.

Organotin complexes of di(2-pyridyl) ketone 2-thenoylhydrazone, 1 and 2, with 6- and 5-coordinated tin atom are less active than the parent organotins\(^{67,68}\). Compound 2 showed good results in tests against *Bacillus subtilis*, *Staphylococcus aureus* and also toward several *Bacilli* with minimum inhibitory concentration ranging from 1.5 to 3 \( \mu\text{gml}^{-1} \).\(^{167}\) At the same time this complex is devoid of DNA-damaging activity in the *Bacillus subtilis* rec-
assay and of mutagenicity in the *Salmonella* test. Organotin complexes \( \text{Ph}_2\text{SnCl}_2\text{L}\cdot2\text{H}_2\text{O} \)\(^{69}\) (\( \text{L} = \text{pyrrole}-2\)-carboxaldehyde 2-hydroxybenzoylhydrazone) and \( \text{Ph}_2\text{Sn}(\text{L-H})\cdot\text{Me}_2\text{SO} \)\(^{70}\) (\( \text{L} = \text{pyrrole}-2,5\)-dicarboxaldehyde bis(2-hydroxybenzoylhydrazone)) have MIC values between 3–6 µg ml\(^{-1}\) against *Bacillus subtilis* and *Staphylococcus aureus* and between 6–25 µg ml\(^{-1}\) against *Escherichia coli*.

Although the ligands of complexes 3 and 4\(^{71}\) are active against *Escherichia coli*, *Pseudomonas syringae*, *Proteus mirabilis* and *Staphylococcus aureus* in the paper disc plate method, their bactericidal effects are smaller as compared with tin derivatives 3 and 4.

The antibacterial activity of heterobimetallic complexes 5\(^{72}\) was determined by the inhibition zone technique (*Escherichia coli*, *Klebsiella aerogenous* and *Pseudomonas*...
cepacica). These complexes are more active than their precursors \((C_5H_7N_3)_2MCl_2\) (\(M = \text{Pd, Pt})\).

### D. Fungicidal Activity

Various organotin derivatives have very high fungicidal activity and, in addition, these compounds show an interesting range of structural variations which allow one to advance some conclusions concerning structure–activity relationships. The fungicidal activity of a series of \(-o, m-\) and \(-p\)-substituted aryltin compounds \((YC_6H_4)_3SnX\)\(^{73,74}\) has been studied by radial growth assays on \(Aspergillus niger\), \(Botrytis cinerea\), \(Mucor hiemalis\), \(Fusarium solani\), and \(Penicillium chrysogenum\). As shown by the ED\(_{50}\) values (Table 2), both \(3\)-\(MeC_6H_4)_3SnOAc and \([3\)-(\(MeOC_6H_4)_3Sn]_2O\) have similar fungicidal effects. They are generally more active than their \(-p\)-tolyl analogues but are still less effective than the parent phenyl biocides already in use, i.e. Brestan (Ph\(_3SnOAc\)) and Du-Ter (Ph\(_3SnOH\)). Two \(-m\)-Me groups, as in \((3,5\)-\(Me_2C_6H_3)\)_3SnOAc, cause an overall decrease in activity — except with \(M. hiemalis\) — and complete loss of activity against \(P. chrysogenum\). In contrast to its \(-p\)-analogue, which is completely ineffective against all the test fungi, \([3\)-(\(MeOC_6H_4)\)_3Sn]_2O is relatively active except with \(P. chrysogenum\). The \(-o\)-tolyl compounds present a less uniform aspect of biological activity. Thus \((2\)-\(MeC_6H_4)\)_3SnOAc is only slightly less effective than \((3\)-\(MeC_6H_4)\)_3SnOAc or \((4\)-\(MeC_6H_4)\)_3SnOAc, but for the oxide the results unexpectedly depend on the fungi being tested. Both trimesityl tin derivatives are ineffective fungicides but they do not promote fungi growth.

The pathogenic fungus \(Ceratocystis ulmi\) (\(C. ulmi\)), responsible for Dutch elm disease, causes a blockade in the vascular tissue that can lead to the eventual death of the

\(^a\)NE = no effect
elm. It has been established that various organotin compounds such as tetraarylstanannanes, triarylchlorostannanes, triphenyltin carboxylates, triphenyltin sulfides, and complexes of triphenylchloro- and triphenylisothiocyanatostannanes with various nitrogen-containing compounds are highly effective in the inhibition of *C. ulmi* (Table 3). The data indicate that all substituted tetraaryl compounds are less effective in the inhibition of the fungus when compared with the parent tetraphenylin. A comparison of the IC50 values for the tetraarylstanannanes Ar₄Sn with those for the triarylstannyl derivatives Ar₃SnX clearly indicates that the latter are far superior in their inhibition of *C. ulmi*.

Diorganotin carboxylates and chlorides have been tested for antifungal activity against *Aspergillus niger*, *Aspergillus flavus* and *Penicillium citrinum* (Table 4). It is evident that diphenylstanannanes are more effective than their dibutyl analogues. Triphenyltin 2-pyrimidylthioacetate Ph₃Sn(OOCCH₂SC₄H₃N₂-2) tested on *Helminthosporium maydis* has greater activity than the tributyltin derivatives. On the contrary, the effect of tributyltin 2-pyrimidylthioacetate Bu₃Sn(OOCCH₂SC₄H₃N₂-2) against *Helminthosporium oryzae* is higher as compared with the triphenyltin compound. Tributyltin hydantooate Bu₃SnOOCCH₂NHC(O)NH₂ is also more effective against spore germination (*Alternaria alternata*, *Helminthosporium sativum*, *Helminthosporium maydis*, *Piricularia oryzae* and *Oryzae sativa*) than the diphenyl and dicyclohexyl derivatives.

N-phthaloyl-protected amino acids react with triorganotin hydroxides to form the hydrated triorganotin carboxylates, which display a wide spectrum of antifungal activity (Table 5). The ED50 values for the tributyltin derivatives generally fall below the 1 ppm range; the ED50 values for the triphenyltin derivatives range from 0.22 to 10.00 ppm, which demonstrates that these compounds possess a higher degree of selectivity in their fungitoxic action.

The organotin derivatives of amino acids having nitrogen-containing heterocyclic rings, i.e. L-histidine and L,D-tryptophan (HL), have been tested in vitro against *Candida albicans*, *Cryptococcus neoformans*, *Sporotrichum schenckii*, *Trichophyton mentagrophytes* and *Aspergillus fumigatus*. The fungicidal activity under experimental conditions decreased in the order: Ph₃Sn > Bu₂Sn > Me₃Sn. Because of the high antifungal effects, they have been screened in vivo against a multi-infection model in mice. However, at 100 mg kg⁻¹ (p.o) these compounds were very toxic, whereas at a dose of 50 mg kg⁻¹ they showed insignificant activity.

Tin derivatives of 4-acetyl and 4-benzoyl-3-methylpyrazol-5-ones (L) were tested to determine the concentrations causing 50% inhibitions of the lateral micelial growth of the six fungi chosen: *Trichoderma viride*, *Colletotrichum gloeosporioides*, *Verticillium fungicola*, *Piricularia oryzae*, *Sclerotinia fruticola* and *Fusarium culmorum*. The general trend of observed fungitoxicity in the test compounds is summarized as R₂SnL₂ < trans-R₃SnL(H₂O) < cis-R₃SnL.

</table>

The effects of diorganotin and triorganotin complexes obtained from various Schiff bases have been evaluated on different species of pathogenic fungi\(^{65,87-90}\).

Besides the discussed types of biological properties, OTCs showed different kinds of biocidal activity, e.g. trypasanocida\(^{91,92}\), herbicida\(^{65}\), insecticida\(^{93-97}\) and ovicida\(^{97}\); they have also toxic effects on fresh water and marine algae\(^{98-100}\).

E. Antitumor Activity

The cytotoxic effect and antitumor activity induced by different organotin compounds have been widely studied. These intensive investigations led to the discovery of compounds with excellent \textit{in vitro} cytotoxic activity. The cytotoxicity of organotin carboxylates with the following structures: RCOOSnR\(_1\)^{1}, (RCOO)\(_2\)SnR\(_1\)^{1} and \{[(RCOO)SnBu\(_2\)]^2O\}_2\), has been tested on several human tumor cell lines (MCF-7 and EVSA-T, two breast tumors; WiDr, a colon carcinoma; IGROV, an ovarian cancer; M19 MEL, a melanoma; A498, a renal cancer). The results of the \textit{in vitro} screening expressed as inhibitory doses (ID\(_{50}\) in ng ml\(^{-1}\)) are presented in Tables 6–8. The majority of presented compounds have activities which are comparable or better than those for cisplatin, 5-fluorouracil, methotrexate and doxorubicin.
TABLE 6.  *In vitro* cytotoxic activities (ID<sub>50</sub>, ng ml<sup>-1</sup>) of tributyl- and triphenyltin carboxylates RCOOSnR<sub>1</sub>\(^3\)

The ID$_{50}$ of 2,6-pyridinedicarboxylatodiorganotin derivatives (16) \((R = R' = Bu, 4-\text{MeOC}_6\text{H}_4, 9-(\text{o-C}_2\text{B}_{10}\text{H}_{11}), 9-(\text{m-C}_2\text{B}_{10}\text{H}_{11}); R = \text{Ph, R'} = \text{Ph, Me, Et, Pr, i-Pr, Bu, i-Bu, Bn})$\textsuperscript{117,118} varied in the wide region from 10 \text{ng ml}^{-1} \text{ for R}=R'=(\text{o-C}_2\text{B}_{10}\text{H}_{11})$ to 4930 ng ml$^{-1}$ \text{ for R}=R'=(\text{4-MeOC}_6\text{H}_4)$ on the MCF-7 cell line.

Anhydrous bis(2,6-pyridinedicarboxylato) dibutylstannane (17)$\textsuperscript{123}$, containing according to X-ray data a 7-coordinated tin atom, was also tested on MCF-7, EVSA-T, WiDr, IGROV, M19 MEL and A498 cell lines and the inhibition doses were found to be 46, 27, 172, 25, 48 and 96 ng ml$^{-1}$, respectively.

The cytotoxic effects of $N$-arylidene [\(\text{OC}_6\text{H}_4\text{C}(R'') = \text{NCHR'}\text{COO}]\text{SnBu}_2$\textsuperscript{124} and ethylene diphosphonate (EtO)$_2$P(O)CH$_2$CH$_2$P(O)(OEt)$_2$•Et$_2$SnCl$_2$\textsuperscript{125} complexes have
been studied against the National Cancer Institute panel of 60 cell lines. These complexes exhibit their highest cytotoxic effect on the NCI-522 (non-small cell lung cancer) cell line. In general, a low to moderate cellular response was observed for all these compounds.

The cyclic derivative of salicylhydroxamide 18 is more active in vitro than cisplatin and 5-fluorouracil against human origin cell lines (MCF-7, EVSA-T, WiDr, IGROV, M19 MEL, A498 and H226), but less active than methotrexate and doxorubicin.

Dibutyl-1,3,2-dioxastannolanes 19–21, including two enantiomeric pairs, were tested in vitro on a variety of human tumor cell lines (HeLa, MM96L, MM418c5, C180-13S). There is no significant difference in cytotoxicity of optical isomers or between compounds 19–22 and dibutyltin dichloride towards HeLa cells (ID$_{50}$ = 0.2–0.5 µM). This lack of difference is consistent with hydrolysis to a common cytotoxic Bu$_2$Sn$^{2+}$ species.

Triphenyltin o-aminophenyl- and 2-pyridylthiolates (2-H$_2$NC$_6$H$_4$SSnPh$_3$ and 2-C$_5$H$_4$NSSnPh$_3$), containing Sn–S bonds, showed high cytotoxicity (ID$_{50}$ = 3–38 ng ml$^{-1}$) on six cell lines (MCF-7, EVSA-T, WiDr, IGROV, M19 MEL and A498) 128.

In the series of [1,2-α]-fused pyrimidin-4-one complexes R$_2$SnCl$_2$$^*$$L^n$ ($R$ = Me, Ph) the most notable activity was demonstrated by the complex with L$^1$ ($R^' = H$, $R'' = CH_2Br$)
against Hep-2, HeLa, RD, BGM cell lines\textsuperscript{129}. The only cell line that was resistant to all complexes was L\textsubscript{20B}. Furthermore, the complex \(\text{Me}_2\text{SnCl}_2\cdot L^3\) (\(R' = \text{MeCOO}\)) showed low cytotoxic activity against the cell lines used (ID\textsubscript{50} > 10 \(\mu\)g ml\textsuperscript{-1}).

In the series of the \(N\)-methyl-2,2\textsuperscript{′}-bisimidazole (MBI) complexes \(R_2\text{SnX}_2\cdot (\text{MBI})\)\textsuperscript{130} (\(R = \text{Me}, \text{Et}, \text{Bu}, \text{Ph}; X = \text{Cl}, \text{Br}\)) the butyl derivatives were the most active against KB (oral epidermoid human carcinoma) cell line. The nature of the halogen bound to the metal atom does not seem to have any influence on activity, except for the butyl complexes, for which the chloride is much more active (ID\textsubscript{50} = 0.023 \(\mu\)g ml\textsuperscript{-1}), than bromide (ID\textsubscript{50} = 0.170 \(\mu\)g ml\textsuperscript{-1}).

The antitumor activity of some organotin carboxylates (7–15) and dibutyltin bisphenylacetate (BnCOO)\textsubscript{2}SnBu\textsubscript{2} (23) was screened on tumor-bearing mice\textsuperscript{101,130,131}. At their maximum tolerated doses, compounds 7–9, 11, 13 and 15 were inactive \textit{in vivo} against colon 26 tumors in Balb/c mice, and carboxylates 10 and 12 showed slight \textit{in vivo} antitumor activity. Compounds 14 and 23 have clear antitumor effect after single dose administration (ratio of the tumor size for the treated mice to that of control mice is 0.51 and 0.42, respectively). The pyridine derivative 16 \([R=R'=9-(m-C_2B_{10}H_{11})]\)\textsuperscript{128} is active \textit{in vivo} against L1210 murine leukemia at doses of 7 and 10 mg kg\textsuperscript{-1}, but toxic at 14 mg kg\textsuperscript{-1}. Noteworthy is that one mouse was cured at a dose of 7 mg kg\textsuperscript{-1}.

The cytotoxic effect and antitumor activity of triethyltin lupinyl sulfide hydrochloride have been investigated\textsuperscript{133}. Different patterns of antiproliferative effects have been observed in a panel of human cell lines \textit{in vitro}. Acute toxicity at doses of 21 and 17.5 mg kg\textsuperscript{-1} in mice was reported and disappeared progressively at lower concentrations. On this base, the doses of 3.5, 7 and 14 mg kg\textsuperscript{-1} were selected to assess the antitumor activity \textit{in vivo} against the P388 leukemic cells xenografted in mice. This compound was able to induce a dose-dependent significant reduction of tumor volume, up to 46\%.

\(R' = \text{H, Me}; R'' = \text{CH}_2\text{Br, MeCOO}\)
Data concerning the abundance of lead in nature, its production and industrial application, toxicology of organolead derivatives, their bioaccumulation, health effects and safety of organolead derivatives were summarized and analyzed in an excellent review2.

The mutagenic activity of triethyllead acetate was determined by measuring the induction of chromosomal aberrations in Chinese hamster ovary cells. The results indicate that Et₃PbOAc is very cytotoxic and a potent clastogen. Test concentrations of Et₃PbOAc for chromosomal aberrations were approximately 10 µM in the absence of, and 80 µM in the presence of, metabolic activation. The maximal response was greater with metabolic activation than without; however, a much higher dose was required to elicit a significant response134.

Effects of triethyllead acetate on the cholinergic system in the brain of the rats were investigated in vitro. At concentrations below 0.1 µM it inhibited the depolarized release of acetylcholine (ACh) from slices of cortex and the synthesis of ACh, while the non-depolarized release of ACh was potent in a dose-dependent manner135.

Low levels of ethyllead compounds (0.1 nM–5 µM) interfere with the normal development of cultured E18 rat hippocampal neurons, probably through increases in intracellular free calcium ion concentration135. Survival of neurons was significantly reduced at 5 µM and the overall production of neurites was reduced at concentrations ≥2 µM. The length of axons and the number of axons and dendrites were reduced at ≥1 µM. Neurite branching was inhibited at 10 nM for dendrites and 1000 nM for axons. Increases in intracellular calcium were observed during a 3.75 h exposure of newly plated neurons at a concentration of 5 µM136.

The neuropathologic effects of low level triethyllead acetate exposure (0.05, 0.10, 0.20, 0.50 and 1.00 mg kg⁻¹ for 91 days, 5 days per week by oral) were studied in male Sprague–Dawley weaning rats. Sections of the central, peripheral and autonomic nervous systems were examined and lesions scored. No lesions were noted in the brain, but randomly distributed light microscopic changes of spinal cord Wallerian degradation were noted to increase in a dose responsive manner. Ultrastructural examination of selected sections of the lumbosacral nerves revealed lesions characterized by reduced neurofilaments and neurotubules, and irregular lamellated axoplasmic dense bodies in all animals receiving lead137. Exposure of neonatal Fischer-344 rats to triethylleads causes permanent hippocampal damage138. Male Fischer-344 rats (>42 days old) were exposed to 8 or 16 ppm of trimethyllead derivatives in drinking water for up to 14 days. The hippocampus was the region very sensitive to organoleads. Control rats had the expected brain regional pattern of glial fibrillary acidic protein (GFAP) concentration with the highest in the hippocampus and cerebellum and lowest in the cerebral cortex. There was significant time-response of GFAP concentration in the hippocampus of rats exposed to 8 ppm dose with decrease on day 7 and increase on day 14139. Comparative observations on organic and inorganic Pb²⁺ neurotoxicity showed a preferential involvement of the hippocampus in both cases, and the clinical syndromes of irritability, hyperactivity, aggression and seizures are common features of disturbed hippocampal function140.

The effects of triethyllead acetate or tetraethyllead, as well as an inorganic lead nitrate Pb(NO₃)₂ on human erythrocytic δ-aminolevulinic acid dehydratase activity was investigated. There was no discernible inhibitory effect of tetraethyllead at any concentration, with and without pre-incubation. Lead nitrate is a much more potent inhibitor of δ-aminolevulinic acid dehydratase activity (0.77 µM) than triethyllead acetate (130.37 µM)141.

Ethyllead compounds in concentrations of 1−10 µM inhibit the proliferation of normal human lymphocytes through decreased expression of the p55 polypeptide chain (Tac
molecule) of the interleukin-2 receptor. The effect of organolead derivatives was also associated with a dose-dependent decrease of the Na\(^{+}\)-K\(^{+}\)-ATPase activity of normal lymphocytes\(^{142}\).

Alkyl leads are environmentally prevalent compounds, which have been shown to produce a variety of neurological and behavioral deficits in both laboratory animals and humans. Heavy abuse of leaded gasoline resulted in an encephalopathy, cerebellar and corticospinal symptoms, dementia, mental status alterations and persistent organic psychosis. However, much of this is due to the hydrocarbons of gasoline, while the tetraethyl lead contributes to the altered mental status and is responsible for the persistent psychosis\(^{143}\).

The influence of organolead compounds on human health was evaluated in clinical tests of organolead manufacturing workers\(^{144−152}\). In March 1990, 222 workers and 62 control group members were administered neurobehavioral tests\(^{144,145}\) that included simple visual reaction time. It was measured over 44 trials; interstimulus intervals ranged from 1 to 10 s in a randomly generated sequence that was identical for all persons. Mean reaction times for both lead-exposed and non-exposed subjects were the longest for interstimulus intervals of 1 and 2 seconds. Mean reaction times in response to moderate (4–6 s) and long (7–10 s) interstimulus intervals were mainly associated with lead exposure and a stronger relationship between reaction time and lead exposure was found. The relations between recent and cumulative exposure to organic and inorganic lead and blood lead level were also examined\(^{146}\). Recent exposure to organic and combined (organic and inorganic) lead was significantly and positively related to blood lead levels. Age and cigarette smoking were positively associated with blood lead levels, whereas alcohol use was associated with lower levels.

To evaluate the connections between tibial lead, dimercaptosuccinic acid (DMSA), chelatable lead and neurobehavioral functions, the clinic investigation of 543 former organolead manufacturing workers (mean age 57.6 years) with an average of 17.8 years since last exposure to lead compounds was undertaken\(^{147,148}\). The average tibial lead concentration in bone mineral was 14.4 µg g\(^{-1}\). DMSA chelatable lead ranged from 1.2 to 136 µg g\(^{-1}\) with a mean value of 19.3 µg g\(^{-1}\). In a multiple linear regression model of tibial lead, age, duration of exposure, current and past cigarette smoking, and diabetes were independent positive predictors, whereas height and exercise inducing sweating were both negative predictors\(^{148}\). Peak tibial lead level was a significant negative predictor of performance on the Wechsler Adult Intelligence Scale-Revised vocabulary subtest, serial digit learning test, Rey Auditory-Verbal Learning Test (immediate recall and recognition), Trail Making Test B, finger tapping (dominant hand, non-dominant hand), Purdue pegboard (dominant hand, non-dominant, both hands, and assembly) and Stroop Test. Moreover, with one exception, average neurobehavioral test scores were poorer at higher peak tibial lead levels\(^{147}\).

This page contains author indices for various names and institutions, each followed by a list of page numbers where they appear. The page numbers are often repeated, indicating multiple occurrences of the same author’s name or related work. The range of page numbers suggests that these are references within a larger document, possibly a book or a journal. The authors are listed alphabetically, likely for easy reference. The document appears to be scholarly in nature, given the comprehensive list of references and the consistent format.

Index compiled by K. Raven
Subject Index

Ab initio calculations,
for complexes of carbene analogues of
Group 14 elements 830–832
for cyclotrigermenes 910
for disilagermirenes 915
for PES of singlet SiH2 and GeH2
reactions 829
for reactions of carbene analogues of
Group 14 elements 822, 824, 825

Absorption spectroscopy,
of GeCl2 757
of GeF2 756, 757
of GeI2 758
of PbCl2 760
of SnCl2 758
of SnF2 758

Acetals — see also Thioacetals
cyclic — see Cyclic acetals

Acetone, heavier Group 14 analogues of,
theoretical studies of 200–202

Acetylenes — see also Polyacetylenes
heavier Group 14 analogues of, theoretical
studies of 191–196
silastannation of 244

Acidities, gas-phase 384

Activation energies 1039, 1052, 1109, 1142,
1195

Adamantanes, organogermainium derivatives
of, neurotropic activity of 1660, 1668, 1669

Addition,
free-radical 1436–1438
homolytic 601–607
intermolecular 1436–1438
intramolecular 1439–1446
nucleophilic 1336–1349
oxidative 673, 675
reverse 1339

Addition/cyclization, tandem 1443, 1444

Alcohols,
secondary — see Secondary alcohols
ω-trichlorostannyl — see
ω-Trichlorostannyl alcohols

Aldehydes, copolymerization with germylenes
1571

Algae, toxic effects on 1697

Alkali metals,
compounds with Group 14 metals — see
M14–alkali metal compounds
triorganogermyl derivatives of, radical
reactions of 582–589

Alkene homologues, structure of 322–334

Alkenes — see 6-Bromo-1-hexene,
Dibromoalkenes, Germacyclocalkenes,
Germapropenes, Phosphaalkenes

Alkenyltin compounds,
coupling reactions of 1352, 1357–1359
transmetallation reactions of 1374
4-Alkoxyalk-2-enylstannanes, reactions of 239,
240

Alkoxygermanes — see also
Methoxygermanes,
Organylalkoxygermanes,
Tris(2-alkoxymethylphenyl)germanes
decomposition of 387
mass spectra of 373

Alkoxtetrahydrofurans, synthesis of 1587

Alkylaminogermanes — see
(Dialkylamino)germanes

Alkylaminostannanes — see
Trialkyl(alkylamino)stannanes

Alkyldihalogermaines, synthesis of 15

Alkyldihaloplumbanes, synthesis of 83

Alkylgermanes — see also
Dialkyldihalogermaines,
Tetaalkylgermaines, Trialkylgermaines
decomposition of 386, 387
synthesis of 8, 15

Alkylgermainium compounds,
photodealkylation of 1524

Alkylgermainium halides, mass spectra of 371

Alkylgermyllithium compounds, synthesis of 9

Alkylhaloaluminanes — see also
Alkyltihaloaluminanes
synthesis of 72

Alkylhalostannanes — see also
Alkyltribhalostannanes
reactions of 36, 47, 48

Alkylidenetelluragermiranes 890
Alkyllead compounds — see Methyllead compounds

Alkyltin compounds, coupling reactions of 1352

Alkyltin halides — see also Alkylhalostannanes, Butyltin trichloride, Trimethyltin chloride mass spectra of 371

Alkyltrihalostannanes, reactions with tin tetrachloride 47

Alkynes — see also Acetylenes copolymerization with germynes 1573, 1574

Alkynylboranes, hydrostannylation of 1449, 1450

Alkynyltin compounds, addition reactions of 1346 coupling reactions of 1351, 1357, 1364, 1367

Allenes — see Germaallenes, Phosphaallenes, Silaallenes, Tristannaallenes

Allenyltin compounds, addition reactions of 1343–1345 coupling reactions of 1352 radical reactions of 1372

Alred–Rochow electronegativity scale 4

Allylation, enantioselective 1341, 1342, 1348, 1349

Allylic derivatives, of Ge and Sn, homolytic addition reactions of 601–607

1,3-Allyl migration, of EH3 substituents 236

Allylstannanes — see also Allyltin compounds, Allyltributyltin, Tetraallyltin addition reactions of 1336, 1337, 1340, 1346–1348 coupling reactions of 1351, 1357, 1364, 1367

Allyltin compounds — see also Allylstannanes, Allyltributyltin, Tetraallyltin addition reactions of 1336, 1337, 1340, 1346–1348 coupling reactions of 1352, 1363 β-functionalized 1342, 1343 radical reactions of 1368–1371, 1373 α-substituted 1340 γ-substituted 1336, 1337, 1340, 1348, 1352, 1369, 1370 substitution reactions of 1382 transmetallation reactions of 1377, 1378

Allyltin, in free-radical reduction of selenides 1421

Allyltributyltin, in free-radical reduction of selenides 1421

Allyltrimethylenes, synthesis of 13

Allyltinorganogermes, photolysis of 605–607

Allyltinorganostannanes, homolytic addition reactions of 603–605 homolytic substitution reactions of 607–610

**Alternaria alternata** 1694

Alzheimer’s disease 1690

Amabilines, synthesis of 1450, 1451

Amidolysis 28

Amines, deamination of 1587 germyl-substituted, neurotropic activity of 1660, 1666 α-Amino acids, synthesis of 1430, 1431 ω-Amino acids — see $N$-2-Hydroxynaphthylidene-$ω$-amino acids, $N$-Salicylidene-$ω$-amino acids

Aminocarboxylic acids, tin complexes of 1615

Aminogermynes — see also Diaminogermynes PE spectra of 805–808

Aminolysis 28

Aminoplumbynes — see also Diaminoplumbynes PE spectra of 805–808

Aminostannynes — see also Diaminostannynes PE spectra of 805–808

Amnesia, retrogradal, control of 1663, 1665, 1667

Anaesthesia, control of 1663–1665, 1667–1669

Anderson row 48

Anilines — see Polyaniline

Anisole, hydrogermylation of 1507, 1508

Anomeric interactions 1420

Anthracenes — see 9-Methylanthracene

Antigenicity, of proxigermanium 1658

Antiknock agents 498

Antimicrobial activity, of organogermanium compounds 1670–1693

Antimycinic activity, of organogermanium compounds 1669, 1670

Antitumour activity, of organogermanium compounds 1670–1675 of organotin compounds 1697–1708

Antiviral activity, of organogermanium compounds 1674, 1675

Aphanius fasciatus 1686

Appearance potentials, of R3M+ cations 634, 635

Aqua complexes 1150, 1156

Arenium σ-complexes 1517

Arenium ions, as intermediates in reactions of trichlorogermane 1489
Arenium salts, of trichlorogermane 1491
Argogel™ polymer 1599
Aromatic bases, as ligands 508, 518
Arylbutenols, synthesis of 1591
Aryldisilanes, photolysis of 1524, 1525
Arylgermanes — see Tetraarylgermanes, Triarylgermanes
Arylgermanium compounds, photolysis of 1525
Arylgermanium halides — see also Aryltrihalogermanes
Arylgermanium compounds, photolysis of 1525
Arylstannanes — see Tetraarylstannanes, Triarylgermanes
Arylstannanes — see also Aryltrihalostannanes
Arylstannatranes, transmetallation with metal alkoxides 1135
Azasteroids, synthesis of 1447
Azastannatranes, transmetallation with metal alkoxides 1135
Azasteroids, synthesis of 1447
Azoephilic dehydoration 1619
Azeotropic dehydration 1619
Bent’s rule 207
Benzenes — see also Dewar benzenes, 1,4-Dimethoxybenzene, Methylbenzenes, Silabenzenes
heavier Group 14 analogues of, theoretical studies of 194, 197, 198
hydrogermylation of 1513
Benzoates — see 2-Benzoylbenzoates
1,4-Benzodiazepines, synthesis of 1599, 1600
2,3-Benz-7-germanorbornadienes, photolysis of 613–616
thermolysis of 613
synchronous mechanism for 616
Benzoic acids — see Retinobenzoic acids
Benzoquinones, copolymerization with germynes 1571, 1572
Benzothiazoles, tin cyanometallates of 1631
2-Benzoylbenzoates, organotin 1610, 1611
Benzvalene 938
Benzyl chloride, reactions with M14–alkali metal compounds 583–587
Benzyltin compounds, coupling reactions of 1352
Berry pseudorotation 1017, 1023, 1051, 1123, 1143, 1187
Bicyclic compounds, formation in cycloadditions of cyclotrimetallenes 917–926
Bidentate ligands 477
BINAP catalysts 1342, 1348
BINOL catalysts 1342, 1345
Bioinorganic systems 522
Biologically relevant ions, models for 477, 481
4,4′-Bipyridine 1624
1,3-Biradicals 618, 627
triplet–singlet conversion of 619
1,5-Biradicals 625
germanium-centred 614, 615, 617
1,6-Biradicals 623, 625, 628
Bis-amidogermylenes, copolymerization with p-benzoquinones 1571
Bis[bis(trimethylsilyl)amidogermylenes, copolymerization with benzoquinones 1572
Bis(chlorodimethylsilyl)diphenylgermane, electroreduction of 1549
Bis(dialkyldithiophosphinato)lead(II) 1635
Bis(dialkyldithiophosphinato)lead(II) 1635
Bis(diaryldithiophosphinato)lead(II) 1635
Bisdimethyl[trans-3-(2-thiophenyl)-2-prope
nato]tin oxide 1614
Bis(halodiorganogeranium)benzene, polymers of 1566
Bis(halodiorganogeranium)thiophene, polymers of 1566
Bis(O-methylidithiocarbonato)lead(II) 1635
Bis(oxazolines) 1371, 1377
Bis(trialkylgermylsulphates, synthesis of 21

Bacillus subtilis 1686, 1691, 1692
π-Back donation 221
Barton–McCombie reaction 1422
Barton reaction 1587
Basis sets 175–177
Bathochromic shifts 870
of ferrocenophanes 1570
Bis(trialkylsilyl)germanes, photolysis of 846
Bis(1,2,4-triazol-1-yl)methane, reactions with diphenyltin bromide 1624
Bis(tributyltin) oxide, toxicity of 1686, 1688
Bis(triethylgermyl)chalcogenides, synthesis of 16
Bis(trimethylgermyl)ferrocene 1570
N,N-Bis(trimethylstannyl)acetamides, tin complexes of 1616
Bis(trimethyltin)carbodiimide 1623
Bis(triorganostannyl)tetrazoles 1625
Bite angles 1055, 1093, 1095, 1104, 1156, 1178
Bond dissociation energies 208, 377
E=E and E=C 183
Bond distances 133, 134
π-Bond energies, in digermenes 852, 853
Bond length difference, as a factor in steric effects 548, 550, 551
Bond polarity 135
Bonds, stability of, C−M, 155, 156
M−H, 156
M−M, 156, 157
M−N, 158
M−O, 157, 158
M−S, 158
M−X, 157
π-Bonds, strength of 183
Boranes — see Alkynylboranes
Botryllus schlosseri 1687
Botrytis cinerea 1693
Branching equations 547, 548
Brestan 1693
3-Bromocamphor, dehalogenation of 1587
6-Bromo-1-hexene, radical reactions of 1415
Butadienes — see Germabutadienes, Polybutadienes, Tetrasilabutadienes
Butenols — see Arylbutenols
Butyltin trichloride, toxicity of 1688, 1689
γ-Butyrolactones, synthesis of 1587, 1589, 1590
C_60, reactions with germyllithiums 714
Caesium trichlorogermaine 13
Cage compounds 935–961
Cage effects 584
Cahours, and the chemistry of organotin compounds 34–37, 39, 43, 44, 46–50, 52, 54, 59, 61
Candida albicans 1694
Carbagermatranes 1069–1071
Carbenes — see Germoxycarbenes
Carbium ions 1511, 1517
Carbocations, as intermediates in reactions of trichlorogermaine 1489
Carbogermanes — see Polycarbogermanes
Carbonates — see Dithiocarbonates, Organotin carbonates, Thionocarbonates
Carbon—carbon coupling reactions 1587
Carbonylation/cyclization 1462, 1463
Carbonyl compounds, nucleophilic addition to 1336–1346
Carbonyl radical acceptor synthon 589
Carbostannanes — see Polycarbostannanes
2-Carboxyethylgermsesquioxane, toxicity of 1658
Carboxylate ligands 1178
Carboxylic acids — see Aminocarboxylic acids, Hydroxycarboxylic acids
Carcinogenicity, of proxigermanium 1658
Cardiovascular activity, of organogermanium compounds 1670
Catenates, conjugated, photolysis of 1525–1529
Cations — see Carbocations, Germaryl cations, Germyl cations, R3M+ cations
Cephalosporins — see Selenocephalosporins
Ceratocystis ulmi 1693, 1695, 1696
CGMT model 321
Chain-growth mechanism 1562, 1563
Chalcogenadigermiranes, synthesis of 852
Chalcogenides — see Bis(trimethylgermyl)chalcogenides
Chalcogenido complexes, of germanium 872, 873
Chalcogenols — see Triethylgermylchalcogenols
Charge-transfer complexes, PE spectra of 150–155
UV spectra of 150–152
Charge-transfer interactions, parameterization of 552
Charge-transfer states 466
Chelate complexes 1171–1199
Chelation, intramolecular, in stabilization of germanium-centred anions 657
Chelation control 1338
Chemically induced dynamic electron polarization (CIDEP) 581, 588
Chemically induced dynamic nuclear polarization (CIDNP) 581, 582, 592, 595–600
Chemical shifts 571
^{73}_{227} Ge 227–229, 401–403
^{207}_{438} Pb 438–447, 685
^{119}_{229} Sn 685
of tin(II) compounds 404–412
of tin(IV) compounds 412–437
Chemical vapour deposition 493
Chemiluminescent emission spectroscopy, of GeCl₂ 757
Chiral carbocycles, synthesis of 1445
Chiral diorganotin dialkylates 1087
Chiral germanes, enzymatic separation of 1403

Cubanes (continued)
  strain energies for 936, 937
  structures of, comparison of 960
Cyanamides 474
Cyanides — see also Organogermainium cyanides, Organolead cyanides, Tin cyanides complexes of 989, 990 reactions of 986
Cyclic acetals, synthesis of 1433
Cyclic digermenes, structure of 851 synthesis of 849
Cyclic diterpenes 332 — see also Cyclic digermenes
Cyclic germasilenes, synthesis of 849
Cyclic germenes, conjugated 870
Cyclic ketones, copolymerization with germynes 1573
Cyclic lead(II) dithiolates, polymeric 1635
Cyclic oligostannanes 1557, 1558, 1564
Cyclic siloxanes 860
Cyclic sulphones, copolymerization with germynes 1571
Cyclic thionocarbonate, free-radical reduction of 1433
Cyclization,
  free-radical 1439–1446, 1463
tandem/cascade 1447–1449
Cycloalkanes — see Cyclopentanes, Cylopropanes, Diorganylplumbacycloalkanes, Diorganylstannacycloalkanes, Germacycloalkanes
Cycloalkenes — see Germanycycloalkenes
Cycloalkyldistannoxanes, reactions of 57
Cyclogermanes — see Cyclotetrameranes, Cyclotrigrimeranes, Perorganlcyclogermaines
Cyclogermirane, stability of 189
Cyclogermoxanes — see also Perorganlcyclergoxanes synthesis of 18, 19
Cyclogermolenanes, synthesis of 25
Cyclohexadienes — see Digermacyclohexadienes
Cyclohexadienes, ring enlargement of 1587
Cyclohexenyl salts, of trichlorogermane 1491
Cyclooctatetraenes, ER3-substituted 236, 237
Cyclo-octamers, structure of 314–319
Cyclopentadienes — see also Germacyclopentadienes EH3-substituted 237, 238
Cyclopentanes — see Germacyclopentanes, Methylcyclopentane
Cyclopentanols — see Germacyclopentanols
Cyclopentenes — see Germacyclopentenes

p-Cyclophanes,
  organo-germanium/-tin-bridged, pyrolysis of 1574
Cyclopolydistannanes 959
Cyclopropanes — see Germacyclopropanes, Germylidene cyclopropane
Cyclopropenes — see Germacyclopropanes
Cyclopropenium cation 927
  heavier Group 14 analogues of, theoretical studies of 194, 196
Cyclostannanes — see Cyclotristannanes, Peralkylcyclostannanes
Cyclostannoxanes — see Perethylylogicyclostannoxanes
Cycloctetrameranes 316
Cycloctetrameranes 952
Cycloctrasilenes 905
Cyclotrialumazine, geometry of 212
Cyclotriborazine, geometry of 212
Cyclotrigallazine, geometry of 212
Cyclotrigermaines — see also Hexamesitylcyclotrimergane
  as cyclopterigermene precursors 907–909 bond lengths in 943
  photolysis of 846
  strain energies 397
Cyclotrigermaines — see also Tetrakis(trialkylysil) cyclotrigermene
  geometry around Ge=Ge bond in 910, 911
  oxidation of 927–931
  structure of 332–334, 336, 851, 906–911
  synthesis of 849, 906–911
Cyclotrigermerium ions 334, 336, 849, 850, 904, 909, 928–931
  aromatic stabilization of 928
Cycloctrimetallanes 903, 904 — see also Cyclotrigrimeranes, Cyclotristannanes theoretical studies of 190
Cycloctrimetallenes — see also Cyclotrigermerines, Cyclotristannenes mixed 913–915
  reactions of 904, 915
  addition 916
  +2cycloaddition 917–923
  +4cycloaddition 923–927
  oxidation 927–931
  synthesis/structure of 904–915
Cycloctrisilanes, strain energies for 937
Cycloctrisilenes,
  bond lengths in 913
  reactions of,
    with CCl4 916
    with phenylacetylene 919
  synthesis/structure of 904–908
Cycloctristannanes 862
  strain energies for 937
  thermolysis of 956, 960
Cycloctristannenes 332, 336, 340, 892, 894
synthesis/structure of 911–913
Cyclovoltammetric measurements, of polymers 1570
Cysteamines, organogermanium derivatives of, toxicity of 1659
Cytochrome P 450, effect of organotin compounds on 1689
Cytotoxic activity, of organogermanium compounds 1671–1674
of organotin compounds 1697–1708

Deamination, using polymer-supported organotin hydrides 1587
Decapeptides, germanium-containing, biological activity of 1677, 1678
β-Decomposition 601
Degermylation 1599
Dehalogenation, using polymer-supported organotin hydrides 1586, 1587
Dehydrochlorination 48
Dehydrocondensation 49, 50, 59, 60
Dehydrofluorination 856, 863
Dehydrogenative coupling, of organostannanes 1561
Dehydroxylation, using polymer-supported organotin hydrides 1587
π-Delocalization, in pyridine ring 216
Demethanative coupling, of trimethylgermane 1550–1552
Denitration 1430, 1431
Density functional theory 172–177
Deoxygenation, using polymer-supported organotin hydrides 1587, 1588
7-Deoxy-6-hydroxyplactatexel 1463, 1464
13-Deoxycyclanodilone 1460, 1461
2-Deoxyuridines, synthesis of 1451, 1452
Dewar benzenes 938—see also Polydialkylgermanes
Dialkylgermylenesulphates, synthesis of 21
Dialkyl(haloacetoxy)plumbanes, synthesis of 82
Dialkylhalogermanes, synthesis of 15
Dialkylplumbanediols, synthesis of 80
Dialkylplumbylenes 866
as thermolytic products of hexaalkylplumbanes 91
Dialkylstannanediols, synthesis of 50, 51
Dialkylstannanes—see also Polydialkylstannanes
reactions of 43
Dialkylstannylamines—see Diethylstannylene, Dimethylstannylene
Diaminogermylenes, IR spectra of 793, 794
reactions of 845
Diaminoplumbanes 865
IR spectra of 793, 794
Diaminostannylanes 892, 894
IR spectra of 793, 794
Diarylplumbylenes 865–867
as thermolytic products of hexaalkyldiplumbanes 91
Dialkylgermylenes,
reactions with elemental tellurium 876
synthesis from germirenes 877
Diyicladicetates 1637
Diarylplumbanes 95, 865–867
Diastereomeric ratios 1086, 1087, 1132, 1186
in triorganotin hydrides 1076, 1077
1,3,2-Diazagermol-2-ylidenes, PE spectra of 808
Diazepines—see 1,4-Benzodiazepines
1,1-Diazido-1-germacyclopent-3-ene,
photolysis of 204
1,3-Diboreanes 855, 856
Dibromoalkanes, hydrostannylation of 1460
Dibromodimethylgermane 629
Dibutyltin bisphenylacetate, antitumour activity of 1708
Dibulutyltin bisphenylacetate, antitumour activity of 1708
Dibutyltin dichloride, toxicity of 1686–1689
Dichlorodimethylgermane 628, 629
Dichlorogermylene—see also GeCl2 complexes of 904, 906–910, 1488, 1490, 1494
free 1494
participation in double gemylation 1502
participation in hydrogermylation 1496
participation in reactions of trichlorogermane with dienes 1499, 1500
Dichlorogermylene–dioxane complex 904
reactions of 906–910
α,ω-Dichlorooligosilanes, polymerizability of 1549
Dicyclopentadienyltin, synthesis of 40
Diels–Alder reactions 919, 923–927 in stannane synthesis 1411, 1413
Diene metathesis reaction 1576
Diienyltin compounds, addition reactions of 1345
coupling reactions of 1357
radical reactions of 1373
transmetallation reactions of 1375
Diethylstannylene — see also Polydiethylstannylene
oxidation of 49
synthesis of 35
Differential scanning calorimetry 1555, 1596
Digermetanes — see Diselenadigermetanes, Dithiadigermetanes
Dihalides, theoretical studies of 177, 178
Dihalodigermerynes, synthesis of 12
Dihalodigermes, reactions with dilithioferrocene 1568
reduction of 846–848
Dihalodigermes 29 — see also Dichlorodigermyle, GeBr2, GeCl2, GeF2,
GeI2
electrochemistry of 809–811
reactions of 12, 13, 845
Dihalotetraalkyldistannanes, synthesis of 1547
Diols, deoxygenation of 1587
Diorganotin bis(fluorosulphate) 1631
Diorganotin dichlorides — see also Dibutyltin dichloride
fungicidal activity of 1694, 1697
Diorganotin dihalides — see also Diorganotin dichlorides, Diorganyldihalostannanes
Digermanes — see also Hexaorganyldigermanes,
Methoxydigermanes, Tetraalkyldigermanes,
antitumour activity of 1674
mass spectra of 364
theoretical studies of 190
Digermylene polymers 1566, 1567
Digermetenes — germyleylene equilibrium 848, 849, 855
Digermenes — germyleylene rearrangement 926
Digermenes 844, 845, 909, 925 — see also Tetraphenyldigermenes
complexes of 1250
cyclic — see Cyclic digermenes
decomposition of 627
reactions of 852–855
with carbon tetrachloride 629
with thiacyloheptynes 626
stable 854, 855
structure of 323–326, 845, 849–851
synthesis of 822–626, 845–849
thermolysis of 853, 854
Digermenoids 907, 909
Digermetanes — see Diselenadigermetanes, Dithiadigermetanes
Diglyme, as cosolvent in synthesis of polygermanes 1547
Dihalides, theoretical studies of 177, 178
Dihalodigermerynes, synthesis of 12
Dihalodigermes, reactions with dilithioferrocene 1568
reduction of 846–848
Dihalodigermes 29 — see also Dichlorodigermyle, GeBr2, GeCl2, GeF2,
GeI2
electrochemistry of 809–811
reactions of 12, 13, 845
Dihalopentamethylene — see PbBr2, PbCl2,
PbClBr, PbF2, PbI2
Dihalostannanes — see also SnBr2, SnCl2,
SnClBr, SnF2, SnI2
electrochemistry of 809–811
1,2-Dihalotetraalkyldistannanes, synthesis of 60
Dihydrobenzothiophene, synthesis of 1445
Dihydroxygermanes 858
1α, 25-Dihydroxyvitamin D2, synthesis of 1449, 1450
Dilithium, germanium-centred 658
Dimerization, in hypervalent compounds 969
organogermanium 980, 1036, 1067, 1140
organotin 970–975, 981, 1000, 1009,
1028, 1088, 1091, 1098, 1102,
1104, 1113, 1132, 1144
of heavy ketones 874, 875, 879, 881, 882, 888
Dimetallenes — see Digermenes, Diplumbenes,
Disilenes, Distannenes, Tetramesityldimetallenes
1,4-Dimethoxybenzene, hydrogermylation of 1509
Dimethylcyclooctatetraenylgermane 1623
Dimethylgermane, IR spectra of 792
Dimethyllead dicyanide 1639
Dimethylstannylene, IR spectra of 792
Dimethyltin bis(fluorosulphate) 1631
Dimethyltin dicyanide 1623
Dimethyltin molybdate 1631
Dimethylthiosulphate 1631
Diols, deoxygenation of 1587
Diorganotin bis(2-naphthyl)thiolates, antibacterial activity of 1690
Diorganotin dichlorides — see also Dibutyltin dichloride
fungicidal activity of 1694, 1697
Diorganotin dicarboxylates, cytotoxic activity of 1702–1704
fungicidal activity of 1694, 1697
Diorganotin dichlorides — see also Diorganotin dichlorides, Diorganyldihalostannanes
Subject Index

chiral — see Chiral diorganotin dihalides
complexes of, with sulphoxide-containing ligands 1617, 1618
Diorganotin disothiocyanates 1633
Diorganotin dithioketones 983

complexes of, with diphosphoryl ligands 1621
Organotin hexacyanoferrates 1628, 1629
Organotin hydrides — see also
Menthylidimethyltin hydrides, Trialkyltin hydrides
as reducing agents 88
polymer-supported 698
reactions of 41–43
synthesis of 41
Organotin hydroxides 972, 987, 1006, 1606 — see also
Trimethyltin hydroxide,
Triphenyltin hydroxide
dimeric 1102, 1103, 1150, 1192, 1199, 1201
Organotin isothiocyanates — see Diorganotin diisothiocyanates,
Organyl(isothiocyanato)stannanes,
Triorganotin isothiocyanates
Organotin malonates 1609
Organotin—nitrogen coordination,
intermolecular 1622–1631
Organotin oxides, polymeric 1577
Organotin—oxygen coordination,
intermolecular 1606–1622
Organotin phosphates 1619
Organotin phosphinates 974, 1619–1621, 1633 — see also Organotin thiophosphinates
Organotin phosphonates 1113, 1619
Organotin—phosphorus coordination 1634
Organotin reagents, leaching of 1585, 1595, 1596
Organotin selenates 1616
Organotin selenides 1616
Organotin sulphides — see Estertin sulphides,
Triphenyltin sulphide
Organotin sulphinates 1616
Organotin sulphites 974, 1032, 1616
Organotin—sulphur coordination 1631, 1633
Organotin thiocyanates — see
Organyl(thiocyanato)stannanes
Organotin thiolates — see Diorganotin dithiolates
Organotin thio phosphinates 1621
Organotin trifluoroacetates 987
Organotin synthesis 69
Organylacetoxygermanes, reactions of 20
synthesis of 20, 21
Organylacetoxyplumbanes 81 — see also
Aryltrieoxyplumbanes,
Diaryldehyoxyplumbanes,
Triarylacetoxyplumbanes
reacylation of 82, 83
synthesis of 82
thermolysis of 73
Organylacetoxystannanes — see also
Dialkyldiacetoxystannanes
reactions of 53
synthesis of 54
Organylalkoxygermanes — see also
Trialkylalkoxygermanes
reactions of 20
synthesis of 19
Organylalkoxyplumbanes — see
Trialkylalkoxyplumbanes
Organylalkoxystannanes — see also
Trialkylalkoxystannanes
synthesis of 53
Organylbromostannanes — see also
Trialkylbromostannanes
reactions of 48
synthesis of 45
Organylcyanostannanes, synthesis of 39, 44
Organylcyanatostannanes, synthesis of 54
Organylcyanoorganogermanes — see
Dimethylcyanoorganogermane,
Trimethylcyanoorganogermane
Organylgermanates,
complexes of 32
synthesis of 20
Organylgermesquienes 25
Organylgermesquithianes — see also
Polyarylgermesquithianes
synthesis of 22
Organylhalogermanes — see also
Alkylidihalogermanes,
Diorganyldihalogermanes,
Organyltrihalogermanes,
Triorganylhalogermanes
complexes of 32
reduction of 15
synthesis of 7, 11, 13, 14
Organylhaloplumbanes — see also
Alkylhaloplumbanes,
Diorganyldihaloplumbanes,
Triorganylhaloplumbanes
complexes of 86, 87
disproportionation of 78
reactions of 69, 70
synthesis of 75
thermolysis of 73
Organylhalostannanes — see also
Alkylhalostannanes,
Diorganyldihealoostannanes,
Organylalkostannanes,
Organylchlorostannanes,

cycloadducts of 921–923
of germacyclopentenes 927
of silole derivatives 920
Oryzae sativa 1694
Osteoporosis, treatment of 1677
Oxathiazapluoboles 883
Oxidation, one-electron, in synthesis of R₃M⁺
cations 637, 638
Oxidation potentials, of Group 14 dimetallanes
638
(3-Oxopropyl)trimethylstannane radical cation
251
(3-Oxybutyl)dibutyltin chloride, toxicity of
1689
Palladium catalysts, in coupling reactions
1349–1365
Paniculatines, synthesis of 1448, 1449
Pauling bond orders 1085, 1124
Pauling relationship 1042, 1083
PbBr₂, vibrational spectra of 786, 789
Pb — C bond, cleavage of 1312
PbCl₂,
electronic spectra of 760
vibrational spectra of 786, 789
PbClBr, vibrational spectra of 787, 789
PbF₂, vibrational spectra of 785, 789
PbI₂,
electronic spectra of 760
vibrational spectra of 789
Pb — N bond 85, 86
Pb — Pb bond, cleavage of 93
Pb — S bond 84, 85
Pb — Se bond 85
Pb — Te bond 85
Penicillium chrysogenum 1693
Penicillium citrinum 1694
Pentacoordinated tin — see also
Pentacoordinate tin complexes
in tricyclic ladder dimers 55
Pentacoordinate germanium complexes,
anionic,
intermolecular 985
spirocyclic 1012–1018
cationic, intramolecular 1139–1144
neutral,
bicyclic 1057–1061
intermolecular 1025
monocyclic 1036–1057
tricyclic 1061–1072
Pentacoordinate lead complexes,
anionic, monocyclic 1010, 1012
neutral,
bicyclic 1122, 1123
intermolecular 1036
monocyclic 1072, 1080, 1082, 1083,
1085, 1116, 1118
Pentacoordinate tin complexes 55
anionic,
intermolecular 985–1004
monocyclic 1005–1011
spirocyclic 1017, 1019–1023
cationic,
intermolecular 1144–1146
intraorganic 1146–1148
neutral, 
bicyclic 1117, 1119–1133 
intermolecular 1025–1035 
monocyclic 1072–1119 
tricyclic 1133–1139

Pentafulvenes, exocyclic Si, Ge and Sn 
derivatives of, theoretical studies of 226, 227

Pentastanna[1.1.1]propellane, formation of 956, 960

Peptides — see Decapeptides
Peralkylycyclostannanes, synthesis of 59
Peralkylyloligogermanes, synthesis of 8
Perethyloligogermanes, synthesis of 8
Perorganylcyclogermanes, synthesis of 18
Perorganylgermthianes, synthesis of 22 — see also Perorganyloligogermthianes
Perorganyloligogermthianes, synthesis of 23
Perorganylpolystannanes, synthesis of 39, 60
Perorganylstannylmetals, synthesis of 61
Perstanna[5]prismane 937

Pharmacological activity 1486
PHASE 401
Phase change properties 561–563

Phenanthrenes — see
Dodecahydrophenanthrenes, 
Germabiphenanthrenes
1-Phenyl-1H-tetrazole-5-thiol 1625
Pheromones, synthesis of 1429, 1430
Phorboxazoles, synthesis of 1449, 1450
Phosphagermenes 351
Phosphicates — see also Organotin 
phosphicates
as ligands 1165
Phosphines — see Tri(2-furyl)phosphine 
Phosphonates — see also Organotin 
phosphonates
as ligands 1165, 1168
C-glycosyl, stereoselective synthesis of 1436, 1437
Phosphorus acids, organotin derivatives of 1619
Photochromic systems 1531
Photoconductors, polygermanes as 1550
Photodegradation, in polygermanes 1550, 1553
Photoelectron spectroscopy, 
of carbene analogues of Group 14 elements, 
polyatomic 805–809 
triatomic 800–805
of charge-transfer complexes 150–155
of solid Sn(II) and Pb(II) halides 803
Photoelimination 1524
Phthalhydrazides — see
Plumbylarenephthalhydrazides
Phthalimides — see Plumbylarenephthalimides
Phthalocyanine complexes, theoretical studies of 223
β-Pinguisene, synthesis of 1422, 1423
β-Pinguisenol, synthesis of 1422, 1423
Piperazine-2,5-diones, tin complexes of 1615, 1616

Piricularia oryzae 1694
Plumbane acids — see Arylplumbane acids
Plumbanediols — see Dialkylplumbanediols
Plumbane esters — see Diorganylplumbane esters, Triorganylplumbane esters
Plumbanes 864 — see also
Dialkyl(haloacetoxy)plumbanes, 
Diplumbanes, Organylacyloxyplumbanes, 
Organylalkoxyplumbanes, 
Organylhaloplumbanes, 
Organyl(organylperoxy)plumbanes,

Polyarylplumbsesquioxanes
Plumbyl anions, reactions with transition metal halides 1308

Plumbylarenephthalhydrazides, synthesis of 86
Plumbylarenephthalimides, synthesis of 86
Plumbylarenesulphonamides, synthesis of 86
Plumbyl compounds, metallated 683

Plumbenes 143, 144, 531, 752, 864, 883, 884 — see also Aminoplumbenes, 
Arylthioplumbenes, Dihaloplumbenes, 
Diorganylplumbenes 
complexes with Lewis bases 753 
ab initio calculations for 830 
electronic spectra of 768, 779, 782 
vibrational spectra of 794–797
Plumbylenes (continued)
dimerization of 816–818, 864, 867–869
heteroatom-substituted 884
heteroleptic 865, 867, 890
insertion reactions of 818–827
polyatomic,
electronic spectra of 766–779
PE spectra of 805–809
vibrational spectra of 790, 793, 794
rearrangement of, intramolecular 815, 816
relativistic effects on 811, 812, 814
singlet excited state of 754
singlet ground state of 753
singlet–triplet splitting in, calculated 812–814
stability of 865–867
intrinsic 815
structure of 296–299, 304
sulphurization of 884, 885, 890
triatomic,
electronic spectra of 753–765
PE spectra of 800–805
vibrational spectra of 782, 785–790
Plumbyl halides, reactions with transition
metal hydrides 1310
Plumbynes — see Diplumbynes
Polyacetylenes, germanium-containing 1600,
1601 — see also Poly[(germylene)diacetylenes]
Polyalkylstannasesquiselenanes, synthesis of 57
Polyaniline, tin cyanometallates of 1631
Polyarylgermsesquithianes, synthesis of 22
Polyarylplumbsesquioxanes, synthesis of 81
Poly[(µ-4,4′-bipyridine)trimethyltin]dimesylamide 1624
Polybutadienes, tin-containing 1585
Polycarborgermanes,
block polymers of 1574, 1575
synthesis of 1573, 1574
Polycarbostananes,
block polymers of 1574, 1575
synthesis of 1576, 1577
Polydialkylgermanes — see Poly(dibutyl)germanes,
Poly(dihexyl)germanes,
Poly(dipentyl)germanes
Polydialkylstannanes — see Poly(dibutyl)stannanes,
Poly(dihexyl)stannanes,
Poly(dipentyl)germanes
Polydialkylstannoxanes, reactions of 53
Polydiarylplumboxanes, synthesis of 81
Polydiarylstannanes 1561–1565
Poly(dibutyl)germanes, synthesis of 1545, 1546
Poly(dibutyl)stannanes 1558, 1561, 1564, 1565
Poly(4-diethylhydrogermane)styrene, synthesis of 1405
Polydiethylstannylene 34
Poly(dihexyl)germanes, synthesis of 1547
Poly(dihexyl)stannanes 1564, 1565
Poly(dimethylsiloxane) 1601
Poly(diocetyl)stannanes 1561, 1563–1565
Polydiorganylstannoxane-α,ω-diols, synthesis of 49
Poly(dipentyl)germanes, synthesis of 1548
Poly(diphenyl-1,4-cis-diénylene) 1568
Poly-2,5-diphenylgermoles 1568, 1569
Polyferrocenylgermanes 1568, 1570
Polyferrocenylstannanes 1574–1576
Polygermanes — see also Polycarbogermanes,
Polydialkylgermanes,
Polyferrocenylgermanes
chemical properties of 1550–1553
conformation of 1553, 1554
electronic properties of 1553–1555
ladder-type 952, 953
mass spectra of 374, 375
photolysis of 1522, 1523, 1553
synthesis of,
by catalytic routes 1549, 1550
by ligand substitution polymerization 1548
by Wurtz-type coupling 1545–1548
electrochemical 1548, 1549
thermochromism in 1554, 1555
Poly[(germylene)diacetylenes],
pyrolysis of 1567, 1568
synthesis of 1567
Polygermyl radicals 1553
Polygermylnes, synthesis of 1547, 1548
Polyhalomethanes, halogen abstraction from 1553
Polyhalomethylchlorogermanes 1553
Polyhedranes 935–961
strain energies for 936, 937
Polymerization — see also Copolymerization,
Cross-polymerization,
Dehydro polymerization
ring-opening 1568, 1574, 1575
Polymerization routes, to polymer-supported
organotin compounds 1581–1585
Polymer resin functionalization route, to
polymer-supported organotin compounds 1579–1581
Polymer, viscosity of 1596
Polymer-supported organogermanium
compounds 1598–1601
characterization of 1598
synthesis of 1598
Polymer-supported organotin compounds,
applications of,
in organic synthesis 1586–1592
in radiopharmaceuticals 1592
Subject Index 1901

in tin dioxide formation 1593, 1595
in tyre manufacture 1579, 1592, 1593
characterization of 1596, 1597
synthesis of 1579–1585
by anionic polymerization route 1585
by monomer polymerization route 1581–1585
by polymer resin functionalization route 1579–1581
Polymetallanes — see also Polygermanes, Polystannanes
σ-delocalization in 1545
Polyorganylgermoxanols, synthesis of 19
Polyorganylgermsesquioxanes, pharmacology of 33
synthesis of 19
Polyorganyl(hydroxy)stannoxanes 52
Polyorganylstannasesquioxanes 52
Polyorganylstannasesquithianes, synthesis of 56
Polyperorganylstannoxane-α,ω-diols, formation of 50, 51
Polypyrrole, tin cyanometallates of 1631
Polyorganylstannates — see also Cyclopolyorganylstannanes, Dodecaorganylpentastannanes, Perorganylpolystannanes, Polycarboorganylstannanes, Polydiarylorganylstannanes, Polyferrocenylorganylstannanes
chemical properties of 1562–1564
cross-linked, formation of 1562
degradation of 1558
electronic properties of 1564, 1565
hyperbranched 1559, 1565
mass spectra of 374, 375
synthesis of 1556–1558
by catalytic routes 1561, 1562
by Würtz coupling 1558–1560
electrochemical 1560, 1561
Polystannasiloxanes 1577, 1578
Polystyrenes — see also Poly(4-diethylhydrogermane)styrene
coupling with tin reagents 1579, 1580
Poly(vinylferrocene) 1570
Poly(p-xylene), germanium-containing, synthesis of 1576
Porcine pancreas lipase 1403
Porphynatogeranium, antitumour activity of 1672
Porphyrines — see also Germylporphyrines
Prismanes 935–949 — see also Hexagermaprismanes, Hexasilaprismanes, Hexastannaprismanes, Perstanna[5]prismane
strain energies for 936, 937
structures of, comparison of 946, 948, 949

tin to copper exchange 1378, 1379
tin to lithium exchange 1374–1378
Triafulvenes, exocyclic Si, Ge and Sn derivatives of, theoretical studies of 226, 227
Trialkylacyloxyplumbanes, reactions of 83
synthesis of 79, 82, 83
Trialkylalkoxygermanes, reduction of 15
synthesis of 19
Trialkylalkoxyplumbanes, reactions of 81, 88
Trialkylalkoxystannanes, reactions of 56
Trialkyl(alkylamino)stannanes, synthesis of 58
Trialkyl(aryl)germanes, mass spectra of 370
Trialkyl(aryl)stannanes, mass spectra of 370, 371
Trialkylbromostannanes, synthesis of 36
Trialkylchloroplobmanes, disproportionation of 77
synthesis of 76
Trialkyl(dimethylamino)germanes, addition reactions of 28
Trialkylgermanes — see also
Trialkyl(alkylthio)germanes, Trialkyl(aryl)germanes,
Trialkyl(dimethylamino)germanes mass spectra of 369
reactions of 19, 261, 265
Trialkylgermanium hydrides — see also
Tributylgermanium hydride synthesis of 1402–1405
use in synthesis 1462–1464
Trialkylhalostannanes — see also
Trialkylbromostannanes
hydrolysis of 52
reactions of 58
with tin tetrachloride 47
synthesis of 36, 44
Trialkyllead hydrides, use in synthesis 1462
Trialkyplumbanes, reactions of 71, 88, 89
Trialkyplumbanols, as irritants 95
reactions of 79
synthesis of 78, 79
Trialkylsilanes, hydrogen abstraction reactions from 261
Trialkylstannanes, hydrogen abstraction reactions from 263, 264
mass spectra of 370
reactions of 42
Trialkylstannanols, dehydration of 52, 53
synthesis of 42
Trialkyl(thiocyanato)plumbanes, synthesis of 85
Trialkyltin hydrides — see also Tributyltin hydride
in non-radical chemistry 1459–1462
in radical chain reactions 1415–1458
synthesis of 1405–1414
Triaryl(alkyl)stannanes, reactions with tin tetrachloride 47
Triarylchlorostannanes, fungicidal activity of 1694
Triarylgermanes, mass spectra of 370
Triaryl(organothio)plumbanes, synthesis of 85
Triarylstannanes, mass spectra of 370
Tribenzylltin 1-phenyl-1H-tetrazole-5-thiolate 1625
Tributylgermanium hydride, synthesis of 1402, 1403
Tributylstannylmagnesium chloride, reactions of 742
Tributyltin acetate, toxicity of 1687
Tributyltin azide 1623
Tributyltin chloride, toxicity of 1687–1689
Tributyltin hydantoate, fungicidal activity of 1694
Tributyltin hydride, as reagent in radical chain reactions 1415
Trichlorogerma,
avid properties of 1488
anion of 1487–1490, 1493, 1503, 1511
electrooxidation of 1492
etherates of 1487, 1490, 1502
metal salts of 1488
organic salts of 1490–1492
physical properties of 1487
radicals of 1503
reactions of, with anisole 1507, 1508
with benzenes 1513–1515
with condensed aromatics 1516, 1517
with conjugated dienes 1498–1500
with cyclopropanes 1501
with 1,4-dimethoxybenzene 1509
with diphenyl ether 1510–1512
with olefins 1494–1498
with organic halides 1493, 1494
with triphenylamine 1512
with $\alpha,\beta$-unsaturated carbonyls 1500, 1501
reactivity of 1489
structure of 1487
superacidic properties of 1488–1490
synthesis of 1487
Wurtz-type coupling of 1547, 1548
$\omega$-Trichlorostannyl alcohols 1607
Trichoderma viridae 1694
Trichophyton mentagrophytes 1694
Tricycloilliconone, synthesis of 1428
Tridentate chelate compounds 477
Triethylgermylchalcogenols, synthesis of 16
Triethylgermylpotassium, synthesis of 9
Triethyllead acetate, biological activity of 1709
Triethyl(organyl)seleno)germanes, synthesis of 25
Triethyltin bromide, toxicity of 1688
Triethyl cyanide 1623
Triflates, coupling reactions of 1354, 1355, 1365
Trifluoroacetylfurans, germyl derivatives of, toxicity of 1659
Trifluoroacetylfurylgermanes, toxicity of 1655
Tri-2-furanylgermane, synthesis of 1403
Tri-2-furanylgermanium hydride, use in synthesis 1462
Tri(2-furyl)phosphine 1351, 1356
1,3,5-Trigermacyclohexane, geometry of 212
Trigermylmethane, geometry of 209
Trihypersilylstannanides 342
Trimethylbis(trialkylsilylamino)plumbanes, synthesis of 86
Trimethylcyanogermane 1623
Trimethyllead azide 1639
Trimethyllead carboxylates 1636
Trimethyllead cyanide 1639
Trimethyllead 2-furoate 1636
$N$-Trimethylstannyl-$N$'-nitrocarbodiimide 1623
$N$-Trimethylstannyl-$N$'-nitromethylamine 1616
Trimethyltin azide 1623
Trimethyltin chloride, toxicity of 1687, 1688
Trimethyltin cyanide 1622, 1623
Trimethyltin dicyanamide 1623
Trimethyltin dithiotetraphenylimidodiphosphinate 1633
Trimethyltin hydroxide, toxicity of 1687
Trimethyltin 1-phenyl-1H-tetrazole-5-thiolate 1625
Triorganolead halides 1635, 1636
Triorganolead sulphonamide 1638
Triorganostannyl derivatives, aliphatic, NMR spectra of 412, 414–420
Triorganotin carboxylates — see also Triorganotin 2-pyrimidylthioacetates, Triphenyltin carboxylates cytototoxic activity of 1698–1701 hydrated, fungicidal activity of 1694
Triorganotin halides — see Chiral triorganotin halides, (3-Hydroxybutyl)dibutyltin chloride, (3-Oxybutyl)dibutyltin chloride, Tributyltin chloride, Triethyltin bromide, Trimethyltin chloride, Triphenyltin chloride
Triorganotin isothiocyanates 1633
Triorganotin 2-naphthylthiolutiates, antibacterial activity of 1690
Triorganotin 2-pyrimidylthioacetates, fungicidal activity of 1694
Triorganylacyloxyplumbanes — see also Trialkylacyloxyplumbanes synthesis of 82
Triorganylaryloxystannanes, synthesis of 53
Triorganyl(dialkylamino)plumbanes, synthesis of 86
Triorganylgermanes — see also Trialkylgermanes, Triarylgermanes, Tri-2-furanylgermane, Tris(2-alkoxyphenyl)germanes as reducing agents 16 reactions of 10 synthesis of 15
Triorganylgermanethiolates, synthesis of 25
Triorganylgermanethiols, synthesis of 24
Triorganylgermanium hydrides — see Trialkylgermanium hydrides, Tri-2-furanylgemimaunium hydrides
Triorganylgermanolates, synthesis of 21
Triorganylgermanols, synthesis of 18
Triorganylhalogermanes, reactions of 23 synthesis of 7
Triorganylhaloplumbanes 86 — see also Trialkylchloroplumbanes
Triorganylhalostannanes — see also Trialkylhalostannanes, Triarylchlorostannanes hydrolysis of 49, 50 reduction of 41
Triorganyl(organic peroxy)plumbanes, reactions of 81
Triorganyl(organicthio)germanes, synthesis of 23
Triorganyl(organylthio)stannanes, synthesis of 57
Triorganylplumbane esters 83
Triorganylplumbanols — see also Trialkyplumbanols
reactions of 80, 82
synthesis of 81
Triorganylstananes — see also Trialkylstannanes, Triarylstannanes
reactions of 42, 43
Triorganylstananols — see also Trialkylstannanols
synthesis of 50
Triorganylstaanylsodium, synthesis of 62
Triphenylamine, hydrogermylation of 1512
Triphenylidifluorostannate 1363, 1382
Triphenylgermyl group, translocation of 1462
Triphenylgermyltrithium, reactions of 10
Triphenylgermylpotassium, synthesis of 9
Triphenylgermylsodium, synthesis of 9
Triphenylisothiocyanatostannanes, complexes of, fungicidal activity of 1694
Triphenyllead dimethyldithiophosphinate 1638
Triphenyllead 2-fluoro-4-nitrosophenolate 1636
Triphenyllead hydroxide 1636
Triphenyltin arylthiolates 1638
cytotoxic activity of 1694
Triphenyltin carboxylates — see also Triphenyltin diethylphosphonocarboxylates
fungicidal activity of 1694
toxicity of 1686–1690
Triphenyltin chloride, toxicity of 1686–1688
Triphenyltin diethylphosphonocarboxylates 1622
Twist angles, in digermenes 850
Ultrasonic, effect on synthesis of polystannanes 1558
Ultraviolet sensitivity, of polygermanes 1553
Ultraviolet spectroscopy, of charge-transfer complexes 150–152
Ultraviolet-visible spectroscopy, of carbene analogues of Group 14 elements 754
Valence isomerization 917, 919
Van der Waals interactions, parameterization of 552
Van der Waals radii 132, 133
in metal complexes 968
Variable-amplitude cross-polarization pulse programs (VACP) 404
Verticillium fungicola 1694
Vibrational spectroscopy 144–149
of Lewis base complexes 794–797
Vinyltin compounds, homocoupling of 1366
radical reactions of 1372
substitution reactions of 1382
Winkler, and the isolation of the element germanium 2, 3, 5
Wurtz–Fittig reaction, in synthesis of organogermainium compounds 7
Wurtz reaction 40, 41
Xanthates, free-radical reduction of 1422–1428
X-ray photoelectron spectroscopy 1553, 1598
X-ray studies, energy-dispersive 1596
of cyclootgermanes 906, 907
of cyclootrisilenes 905
of cyclicotannanes 911, 912
digermenes 845, 851
distannenes 861, 862
germsenes 856, 857
of heavy ketones 887, 888
of M14 anions 683, 684
α,β-Unsaturated ketones, copolymerization with germynes 1571, 1573
Uracils, organogermainium derivatives of, antitumour activity of 1671, 1672
Ureas — see Germachalcogenoureas, Nitrosoureas
Uridines — see 2-Deoxouridines
of transition metal–germanium double bond 1273
of transition metal–germanium single bond 1271–1273
of transition metal lead complexes 1315–1317
of transition metal–tin single bond 1303–1305
Xylenes — see Poly(p-xylene)
Zinc dialkyls, in synthesis of organolead compounds 68, 69
Zirconocenes, as catalysts, in synthesis of polygermanes 1550
Zwitterions 1148, 1154, 1201

germanate 1149
in copolymerization of germynes 1572
spirogerminate 1023
stannate 1004

Index compiled by P. Raven
Contents of Volume 1

1  The nature of the C–M bond (M = Ge, Sn, Pb) .......................... 1
   H. Basch and T. Hoz

2  Structural aspects of compounds containing C–E (E = Ge, Sn, Pb) bonds .......................... 97
   K. M. Mackay

3  Stereochemistry and conformation of organogermanium, organotin and organolead compounds .......................... 195
   J. A. Marshall and J. A. Jablonowski

4  Thermochemistry of organometallic compounds of germanium, tin and lead .......................... 245
   J. A. Martinho Simões, J. F. Liebman and S. W. Slayden

5  ESR of organogermanium, organotin and organolead radicals .......................... 267
   J. Iley

6  Photoelectron spectroscopy (PES) of organometallic compounds with C–M (M = Ge, Sn, Pb) bonds .......................... 291
   C. Cauletti and S. Stranges

7  Analytical aspects of organogermanium compounds .......................... 339
   J. Zabicky and S. Grinberg

8  Analytical aspects of organotin compounds .......................... 365
   J. Zabicky and S. Grinberg

9  Analytical aspects of organolead compounds .......................... 429
   J. Zabicky and S. Grinberg

10 Syntheses of M(IV) organometallic compounds where M = Ge, Sn, Pb .......................... 453
    J. M. Tsangaris, R. Willem and M. Gielen

11 Acidity, complexing, basicity and H-bonding of organic germanium, tin and lead compounds: experimental and computational results .......................... 537
    A. Schultz and T. A. Klapötke
Contents of Volume 1

12 Substituent effects of germanium, tin and lead groups 603
   M. Charton

13 The electrochemistry of alkyl compounds of germanium, tin and lead 665
   M. Michman

14 The photochemistry of organometallic compounds of germanium, tin and lead 723
   C. M. Gordon and C. Long

15 Syntheses and uses of isotopically labelled organic derivatives of Ge, Sn and Pb 759
   K. C. Westaway and H. Joly

16 The environmental methylation of germanium, tin and lead 843
   P. J. Craig and J. T. van Elteren

17 Toxicity of organogermainium compounds 857
   E. Lukevics and L. M. Ignatovich

18 Organotin toxicology 865
   L. R. Sherman

19 Safety and environmental effects 871
   S. Maeda
